Abstract

Large Language Models (LLMs), despite their recent impressive accomplishments, are notably **cost-prohibitive** to deploy, particularly for applications involving long-content generation, such as dialogue systems and story writing. Often, a large amount of transient state information, referred to as the **KV cache**, is stored in GPU memory in addition to model parameters, **scaling linearly** with the **sequence length and batch size**. In this paper, we introduce a novel approach for implementing the KV cache which significantly **reduces** its **memory footprint**. Our approach is based on the noteworthy observation that a **small portion of tokens contributes most of the value** when computing attention scores. We call these **tokens Heavy Hitters (H₂)**. Through a comprehensive investigation, we find that (i) the emergence of H₂ is natural and strongly correlates with the **frequent co-occurrence of tokens in the text**, and (ii) **removing them** results in significant performance **degradation**. Based on these insights, we propose Heavy Hitter Oracle (H₂O), a **KV cache eviction** policy that dynamically retains a balance of recent and H₂ tokens. We formulate the KV cache eviction as a dynamic submodular problem and prove (under mild assumptions) a theoretical guarantee for our novel eviction algorithm which could help guide future work. We validate the accuracy of our algorithm with OPT, LLaMA, and GPT-NeoX across a wide range of tasks. Our implementation of H₂O with 20% heavy hitters improves the **throughput over** three leading inference systems DeepSpeed Zero-Inference, Hugging Face Accelerate, and FlexGen by up to 29×, 29×, and 3×

on OPT-6.7B and OPT-30B. With the same batch size, H₂O can **reduce the latency by up** to 1.9×.

1. Introduction

Large Language Models (LLMs) have demonstrated remarkable proficiency in a wide range of natural language processing applications such as content creation, summarization, and dialogue systems (Thoppilan et al., 2022; Yuan et al., 2022; Wei et al., 2022a; Zhang et al., 2023). However, their deployment is very costly. In addition to the widely-studied bottlenecks of model size and the **quadratic cost of attention** layers, the problem of the size of the KV **cache**, which stores the intermediate attention key and values during generation to avoid re-computation, is becoming **increasingly prominent** (Pope et al., 2022). For instance, a 30 billion-parameter model with an input batch size of 128 and a sequence length of 1024 results in 180GB of KV cache. A natural approach is to **limit its maximum size** as is done in classical software or hardware caches (Belady et al., 1969). However, it is challenging to reduce KV cache memory footprints in LLMs without accuracy drops.

While there exists a substantial literature on **sparse attention** approximation in training, they have not seen wide adoption for **alleviating** KV cache **bottleneck**. First, most existing methods, e.g., Reformer (Kitaev et al., 2020), Flash Attention (Dao et al., 2022), and Performer (Choromanski et al., 2020), are designed to **overcome the quadratic memory** required by attention mechanisms when **modeling long sequences** but still **require a large cache size**. Second, variants like sparse transformers (Child et al., 2019) or multi-query attention (Shazeer, 2019; Chowdhery et al., 2022; Pope et al., 2022) can **reduce the cache size**, but directly applying them on pre-trained LLMs for generation results in **high miss rates** and **degrades the accuracy** as shown in Figure 1. Finally, some recent advances such as gisting tokens (Mu et al., 2023) can learn to **compress the KV cache** for documents, but their **expensive eviction policies** are difficult to deploy during generation.

Therefore, an ideal KV cache should have (i) a **small cache size** to reduce memory footprint, (ii) a **low miss rate** to maintain the performance and long-content generation ability of LLMs, and (iii) a **low-cost eviction policy** to reduce the wall-clock time during generation. However, there are

Figure 1: Left: the overview of H₂O framework. Right: the comparison of the accuracy-memory trade-off across different KV cache policies in LLM generation and the symbolic plots of their corresponding attention maps.

three technical challenges. First, it is not immediately clear whether the size of the KV cache can be restricted—each decoding step might, in principle, require access to all previous attention keys and values. Second, identifying an optimal eviction policy that maintains generation accuracy is a combinatorial problem¹. Finally, even if an optimal policy can be brute-forced, it is infeasible for deployment on real-world applications.

Fortunately, our preliminary exploration has yielded intriguing observations about the empirical properties of LLMs. These findings pave the way for the potential design of an efficient KV cache.

Sparsity for small cache size: We observe that even when trained densely, the attention matrices of LLMs are over 95% sparse at inference time (shown in Figure 2). This holds for a wide range of pre-trained LLMs. Therefore, only 5% of the KV cache is sufficient for decoding the same output token at each generation step, which suggests it may be possible to have up to a 20× reduction in KV cache size without an accuracy drop.

Heavy-Hitters for low miss rate: We discover that the accumulated attention scores of all tokens in attention blocks adhere to a power-law distribution. It suggests that there exists a small set of influential tokens that are critical during generation, named heavy-hitters (H₂). H₂ provides an opportunity to step away from the combinatorial search problem and identify an eviction policy that maintains accuracy.

Greedy algorithm for low-cost policy: we surprisingly find that retaining the H₂ based on local statistics at each decoding step—summing the attention scores of only the preceding tokens—is as effective as considering the attention of future tokens (shown in Figure 2).

Based on the above, we first rigorously define the generative process of LLMs operating with a size-constrained KV cache in Section 2. Then we propose Heavy-Hitter Oracle (H₂O), a framework that exploits the properties of LLMs and uses simple, low-cost eviction policies that retrain the quality of LLMs throughout the generation process:

- In Section 3, we explore the emergence of H₂ in attention, revealing their fundamental and critical roles: (i) H₂ exhibit a strong correlation of frequently co-occurring

words in textual data; and (ii) removing H₂ completely damages the model’s functionality. We demonstrate that H₂ can largely lower the cache miss rate of the existing policies mentioned above. Theoretically, assuming the attention scheme is submodular, H₂ corresponds to a greedy algorithm and is therefore near-optimal.

- In Section 4, we present a greedy but low-cost variant of H₂ which is dynamically determined by the accumulated attention score at each decoding step. We formulate the eviction policy with greedy H₂ as a variant of dynamic submodular maximization. The analysis shows that it results in a similar generative process as the one using the H₂ eviction policy.

We perform extensive experiments on OPT, LLaMA, and GPT-NeoX on a single NVIDIA A100 (80GB) GPU to evaluate H₂O across a range of tasks from lm-eval-harness (Gao et al., 2021) and HELM (Liang et al., 2022). We implement H₂O on top of FlexGen that can easily adapt different cache eviction techniques to produce a system with high-throughput inference. Performance experiments show our framework achieves 29×, 29×, 3× higher throughputs compared to three leading inference systems, DeepSpeed Zero-Inference (Aminabadi et al., 2022), Hugging Face Accelerate (HuggingFace), and FlexGen (Sheng et al., 2023) respectively. With the same batch size, H₂O achieves up to 1.9× lower latency compare to FlexGen.

2. Problem Formulation

We formally define the generative process with limited KV cache size. Denote attention query matrix as $Q \in \mathbb{R}^{n \times d}$ and key matrix as $K \in \mathbb{R}^{n \times d}$. $Q_{i,*}$ represents the i -th row of Q and $K_{\leq i,*}$ represents the first i rows of K . Let k denote the budget of space and $k < n$. For simplicity, $K_{S_i,*}$ denotes a sub-matrix of K which selects S_i rows from K . Eviction policy is defined as:

Definition 2.1 (Eviction Policy, informal). Let S_{i-1} denote the source set. Let S_i denote the target set. We defined the eviction policy $g : S_{i-1} \rightarrow S_i$ such that

- $|S_i| = k$ (KV cache size is not changing over the time)
- $|S_i \setminus S_{i-1}| \leq 1$ or equivalently $|S_i \cap S_{i-1}| \geq k - 1$ (we can evict at most 1 KV in the KV cache)

Then we define the generative process:

Definition 2.2 (The generative process with eviction policy, informal). Let k denote the size of the KV cache. For each

¹Belady’s Algorithm is optimal for standard cache, but not necessarily for KV cache.

$i \in [n]$, for the i -th token, we have

- Let $S_i \subset [n]$ denote the tokens in KV cache when predicting the i -th token.
- The information we have is a length- i vector $o_i := D_i^{-1} \cdot \exp(Q_{i,*}(K_{S_i,*})^\top)$ (normalized attention)
 - scalar $D_i := (\exp(Q_{i,*}(K_{S_i,*})^\top) - 1_{[i] \setminus S_i}) \cdot \mathbf{1}_i$ (the evicted KV is set to 0, and we need to subtract them when computing the normalization)
 - Replacing S_i by $[i]$ in the above definition of o_i and D_i leads to standard generative process.

- The eviction policy (Definition 2.1) updates S_i based on S_{i-1} and their corresponding information.

Remark 2.3. Our goal is to find a KV cache eviction policy such that the output of the generative process is **similar or comparable to the original one with full cache size**.

3. Observations

We present two key empirical insights of LLMs that inspire the design of H₂O, as follows. More details and analysis can be found in Appendix C.

3.1. Sparsity for Small Cache Size

We first show an observation on the sparsity of attention in pre-trained LLMs. Then we discuss how it can potentially unlock the possibility of reducing KV cache size **without an accuracy drop**. As shown in Figure 2 (a). We observe that although the LLMs are densely trained, the resulting **attention score matrices are highly sparse**, with a sparsity over 95% in almost all layers. Such sparsity indicates the redundancy in KV cache and it is possible to **evict unessential KV embeddings** and reduce the requirement of KV cache during generation.

3.2. Heavy-Hitters for Low Miss Rate

Despite the sparse nature of attention blocks in pre-trained LLMs, determining the best eviction policy that preserves generation accuracy presents a combinatorial challenge, and **evicting important KVs could destroy the performance of LLMs due to the sequential dependency** of LLM generation. Fortunately, in the early stage of our exploration, we find that **the accumulated attention scores of all the tokens within attention blocks follow a power-law distribution**, as shown in Figure 2. This suggests the existence of **a small set of tokens that are critical during generation**. We denote those tokens as heavy-hitters (H₂). And removing H₂ causes significant accuracy drops. Based on H₂, we design a KV cache eviction policy that **retains only the H₂ and the recent KV embeddings in the cache**. Such eviction policy can largely reduce the KV cache size without degrading the performance, as shown in Figure 2. Moreover, we find that H₂ based policy is related to the classical greedy algorithm (a polynomial-time algorithm with provable guarantees) under the assumption that the attention scheme is submodular. We present details in Appendix F.

Lemma 3.1 (informal). Assuming the attention scheme is submodular, then greedily constructing the set S_i (without cache size limitation) satisfies the near-optimal property in terms of submodular.

4. Heavy-Hitter Oracle

The goal of this section is to propose the greedy algorithm using the H₂-based policy and to show the provable guarantees. We first present the H₂-based policy called H₂O cache eviction policy and formulate its deployment in LLM generation as a variant of submodular maximization problem, named *dynamic submodular*. Then we present H₂O in the generative process. Finally, we provide theoretical guarantees for H₂O and show our efficient system implementation.

4.1. Greedy Algorithm for Low-Cost Policy

We have shown a simple yet effective KV cache policy based on H₂. However, it is **impractical** to deploy such an algorithm because we do **not have access to the future** generated tokens. Fortunately, we empirically observe **that local H₂**, which is calculated using local statistics **at every decoding step by summing up the attention scores of the previous tokens**, is equally effective as taking into account the attention of future tokens (Figure 2). In the following, we formally define this dynamic attention score computation (with space limitation) as a novel dynamic submodular type problem.

Definition 4.1 (Dynamic submodular framework, informal). Define function $F : 2^{[n]} \times 2^{[n]} \rightarrow \mathbb{R}$, then for any set $Z \subset [n]$, we assume that $F(Z, \cdot) : 2^{[n]} \rightarrow \mathbb{R}$ is a submodular function w.r.t. to Z , i.e.,

- For all sets $X, Y \subset [n]$ satisfy that $Z \subset X \subset Y$,
- For all element $x \in [n]$ satisfy that $x \in [n] \setminus Y$,

we have $f(X \cup \{x\}) - f(X) \geq f(Y \cup \{x\}) - f(Y)$, where $f(\cdot) := F(Z, \cdot)$.

Remark 4.2. We provide practical insights of Definition 4.1. X denotes **the existing words in the KV cache**. Y is any **superset of X** . x can be **viewed as a “word” which is either newly added to or existing deleted from KV cache**. An example f can be attention score, i.e., see Algorithm 1.

If we load the sequence of S_1, S_2, \dots, S_n (we promise that $|S_i| \leq k$ and $|S_i \setminus S_{i-1}| \leq 1$) into Definition 4.1, i.e., for each $i \in [n]$, we choose $Z = S_i$, then it becomes a particular instance of the dynamic submodular problem.

Next, we provide a formal description of our algorithm.

Definition 4.3 (H₂O Eviction Policy). Let $F_{\text{score}} : 2^{[n]} \rightarrow \mathbb{R}$ denote certain score function. Let S_{i-1} denote the source set. Let S_i denote the target set. We defined the eviction policy $g : S_{i-1} \rightarrow S_i$ s.t.

- $|S_i| = k$ (KV cache size **is not changing over** the time)
- $|S_i \setminus S_{i-1}| \leq 1$ or equivalently $|S_i \cap S_{i-1}| \geq k - 1$ (we **can evict at most 1** KV in the KV cache)
- We construct $S_i \leftarrow (S_{i-1} \cup \{i\}) \setminus \{u\}$ as $u \leftarrow \arg \max_{u \in (S_{i-1} \cup \{i\})} F_{\text{score}}(S_{i-1} \cup \{i\} \setminus \{u\})$

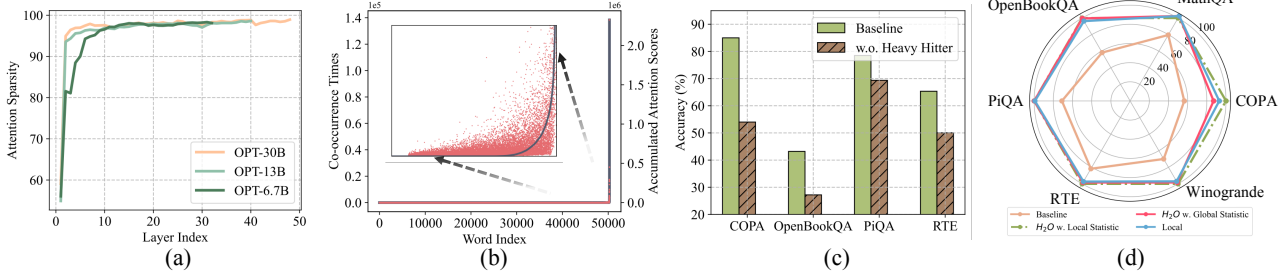

Figure 2: (a) Attention Sparsity in pre-trained OPT models. (b) The distribution of accumulated attention scores with respect to the corresponding word (red scatter) and the co-occurrence times of words in the data (gray curve). The x-axis represents the word index in the vocabulary. (c) The performance comparison between the baseline model with full KV and the model *w.o.* heavy hitter. (d) Comparison between the baseline model with full KV, H₂O with the local statistic, H₂O with the global statistic, and the model with only the most recent KV (Local). Apart from the baseline model, each model is evaluated with 20% KV cache budget.

We choose a particular instantiation of the function F_{score} , *i.e.*, the summation of that sets in the attention matrix, and describe our H₂ eviction policy in Algorithm 1. We also provide an illustrative example in Appendix D.

13:       $S_i \leftarrow (S_{i-1} \cup \{i\}) \setminus \{u\}$ 
14:     end if
15:   end for
16: end procedure

```

4.2. Theoretical Guarantee and System Implementation

We state a theoretical result as follows. The proofs and more details are provided in Appendix F.

Theorem 4.4 (informal). *Under the mild assumption, let k denote the budget of space limitation. If for each token, we greedily compute the attention score based on top- k choice, then we can show the set \tilde{S}_i we generate each for token i satisfy that $f(\tilde{S}_i) \geq (1 - \alpha)(1 - 1/e) \max_{|S|=k} f(S) - \beta$, where $\alpha, \beta > 0$ are parameters.*

Remark 4.5. We remark the above theorem provides a theoretical explanation of why can we hope our greedy algorithm (with cache limitation) can provide a good solution.

Implementation Details. We provide a general framework that can support any KV cache eviction algorithm and enhance throughput and reduce latency of LLM generation with careful implementation. More details are included in Appendix A.

5. Empirical Evaluation

In this section, our goal is to demonstrate that H₂O, a remarkably simple KV cache eviction policy is capable of enhancing end-to-end throughput and reducing latency in wall-clock while maintaining generation quality across a broad spectrum of domains and tasks. We summarize the key results as the following and report all implementation details and complete experiment results in Appendix A and E, due to the space limitation.

- In Appendix E.1, we show that H₂O can reduce the memory footprint of KV cache by up to 5× without accuracy degradation on a wide range of model architectures (OPT, LLaMA, GPT-NeoX), sizes (from 6.7B to 175B) and evaluation benchmarks (HELM and lm-eval-harness). More importantly, can enhance the performance of existing KV cache sparsification techniques.
- In Appendix E.2, we demonstrate that H₂O can increase the inference throughput by up to 3×, 29×, 29× compared to the state-of-the-art inference engine FlexGen, DeepSpeed and the widely used Hugging Face Accelerate without compromising model quality.
- In Appendix E.3, we present extensive ablation studies to show the effectiveness of H₂O under different sequence lengths, and its compatibility with quantization.

6. Conclusion and Discussion

In this paper, we study one of the key bottlenecks of LLM deployment, KV cache, particularly for long-content and large-batch generation applications. We propose H₂O, a simple KV cache eviction policy for significantly reducing its memory footprint. The main insight of our approach is the recognition of a subset of tokens, known as Heavy Hitters, which contribute the most value when computing attention scores. We formulate the KV cache eviction as a dynamic submodular problem and provide the theoretical guarantees for our algorithm. Through extensive evaluations, we demonstrate that H₂O can significantly improve end-to-end throughput and decrease latency in wall-clock time, without compromising the generation quality of LLMs across a variety of tasks.

A. More Implementation Details

In this section, our goal is to provide the details of system implementation (mentioned in Section 4.2) and experiment settings (mentioned in Section 5), as well as the pseudocode.

System Details. We implement H₂O on top of FlexGen. FlexGen is a white-box implementation of OPT models, and we have done some surgery on handling the KV cache. Specifically, for the given parameter k , we always maintain a list of KV cache with the first k entries as heavy hitters, and the last k entries as most recent tokens. In order to avoid data movement in memory, the memory for KV cache is preallocated. We use a circular queue to efficiently update the last k entries.

Experiment Details. Our study involves the evaluation with varying sizes of KV cache that encompass 4%, 10%, 20%, and 60% of the prompt’s length. We select two tasks (XSUM and CNN/Daily Mail) from the HELM framework (Liang et al., 2022) and present the performance based on 1000 test samples. Additionally, we employ the lm-eval-harness framework (Gao et al., 2021) for six other tasks (COPA, MathQA, OpenBookQA, PiQA, RTE, and Winogrande). For the tasks derived from the HELM framework, we report the performance for zero-shot inference, while for the tasks from lm-eval-harness, we default to conduct five-shot inference.

Pseudocode. We show some pseudocode to demonstrate our implementation skeleton. The function `generation_loop()` is the base loop in FlexGen that controls prefetch and overlap the I/O streams and computation. Then in function `compute_layer()`, the function `attention_forward()` will be called for attention layers. The function `compute_attention()` will return new KV cache and the indices for evicted entries during decoding iterations, which would be the place to implement customized evict strategy. During each decoding iteration, the oldest one among last k tokens will be removed from the reserved last k entries, one heavy hitter will be evicted for each head, and the newest token will be added to the KV cache with a position in the last k entries. This happens in the function `store_cache()`.

```
def generation_loop(...):
    # Prologue
    ...
    # Generate
    for i in range(gen_len):
        for j in range(num_layers):
            for k in range(num_gpu_batches):
                load_weight(i, j+1, k)
                load_cache(i, j, k+1)
                store_hidden(i, j, k-1)
                load_hidden(i, j, k+1)
                compute_layer(i, j, k)
                store_cache(i, j, k-1)
                sync()
    # Epilogue
    ...

# h is the hidden states (activations)
def attention_forward(h, ...):
    # The read/write buffer are intermediate stops for prefetching
    if prefill:
        h, new_k_cache, new_v_cache = compute_attention(h, ...)
        cache_write_buffer.store(new_k_cache, new_v_cache)
    else:
        k_cache, v_cache = cache_read_buf.pop()
        # evict_ids track the entries that will be evicted
        h, new_k_cache, new_v_cache, evict_ids =
            compute_attention(h, k_cache, v_cache, ...)
        cache_write_buffer.store(new_k_cache, new_v_cache, evict_ids)
    return h

def store_cache(...):
    if prefill:
        # store cache directly
```

```

...
else:
    k_new, v_new, evict_ids = cache_write_buffer.pop()
    # circular queue for the last K entries
    # extract the index for the oldest token at i-th iteration
    oldest = ((i - 1) % K) - K
    # update the KV cache (k_home and v_home)
    cache_replace(k_home, evict_ids, k_new, K, oldest)
    cache_replace(v_home, evict_ids, v_new, K, oldest)

```

B. Related Works, Discussions, and Limitations

The goal of this section is to first introduce the background and related works, then describe some previous attempts in our experiments as well as discuss the social impact and limitations of this work.

B.1. Related Works

Efficient Inference of LLMs. The substantial parameter counts of large language models (LLMs) present significant challenges for inference. To overcome this limitation, previous efforts have employed model compression techniques with specific designs to achieve efficient LLM inference, such as the method described in (Frantar & Alistarh, 2023), which employs one-shot pruning on LLMs (e.g., OPT-175B and BLOOM-176B), resulting in negligible performance degradation even without retraining. Additionally, alternative approaches explore quantization methods specifically tailored to LLMs, as discussed in (Frantar et al., 2022; Xiao et al., 2022; Yao et al., 2022; Dettmers et al., 2022b;a). These methods address efficient inference from orthogonal perspectives and can be organically integrated. The techniques investigated in this study are closely associated with pruning or sparsity but focus on a distinct inference bottleneck, namely, KV cache. One closely related work (Anagnostidis et al., 2023) utilizes a learnable mechanism that determines necessary tokens during inference but requires an extra fine-tuning process, which makes it less practical. And (Wang et al., 2021) follows the same heuristic to select the most important tokens via attention scores, yet focus on relatively small-scale tasks.

Quantization, Pruning, Distillation for Inference. Previously, model compression algorithms have been extensively investigated as a viable approach for mitigating the computational resource requirements of model inference. These algorithms can be broadly categorized into three groups: (1) quantization (Han et al., 2015; Jacob et al., 2018; Nagel et al., 2019; Zhao et al., 2019), which involves mapping model parameters or activations from high-precision data types to low-precision counterparts, such as using 8-bit integers instead of the commonly employed 32-bit floating point format; (2) pruning or sparsity (Molchanov et al., 2016; Liu et al., 2018; He et al., 2019; Hoefler et al., 2021), which aims to eliminate unnecessary neurons or weights within the models; (3) and distillation (Hinton et al., 2015; Cho & Hariharan, 2019; Tang et al., 2019; Touvron et al., 2021) where predictions from larger models are utilized as supervised information to train smaller models.

Transformer in NLP. Transformers (Vaswani et al., 2017) as a popular option have been frequently adopted by plenty of natural language processing (NLP) applications with prevailing successes (Yang et al., 2019b; Liu et al., 2019b; Talmor et al., 2018; Jaiswal et al., 2021; Yang et al., 2019a; Wang et al., 2018; Ding et al., 2019; Chowdhery et al., 2022; Wei et al., 2022b; Yang et al., 2023). Roughly, modern transformer-based networks can be categorized into two groups: (1) Encoder-Decoder or Encoder-only (*i.e.*, BERT-style models (Devlin et al., 2018)). This type of transformers commonly leverages the Masked Language Modeling task which encourages models to capture the intrinsic relationship between words and their context. Notable examples include BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019b) and T5 (Raffel et al., 2020). (2) Decoder-only (*i.e.*, GPT-style models (Radford et al., 2019)). Usually, this group of transformers adopts the Casual Language Modeling task, which is optimized to generate the next word/token in a sequence based on the preceding words/tokens. Such an autoregressive manner is highly preferred by downstream tasks like text generation and question answering. GPT-3 (Brown et al., 2020), OPT (Zhang et al., 2022), PaLM (Chowdhery et al., 2022), and BLOOM (Scao et al., 2022) are representative architectures within this huge family.

Training of Transformer. Training a gigantic transformer-based model is not trivial. It notoriously suffers from various issues such as overfitting, instability, etc. (Zhang et al., 2020; Liu et al., 2019a; 2020a) analyze these bottlenecks from the optimization perspective. To address the issues, a great amount of pioneering effort is devoted, including data augmentations (Variš & Bojar, 2021; Zhang & Vaidya, 2021), a better initialization (Liu et al., 2020b;a; Xu et al., 2020; Zhu

et al., 2021), customized optimizers (Cohen et al., 2022), improved normalization (Wang et al., 2022; Yang et al., 2022), weight decay (Loshchilov & Hutter, 2017), and early stopping. However, there is still a long way to go before we can fully clarify the mystery of transformer training.

Sparse, Low-rank Attention Approx. The quadratic computational complexity of attention modules is one of the major bottlenecks of transformer inference (Tay et al., 2020). Various efforts are devoted to addressing this challenge (Kitaev et al., 2020; Child et al., 2019; Choromanski et al., 2020). For example, Reformer (Kitaev et al., 2020) reduces the computational cost from quadratic to superlinear complexity via locality-sensitive hashing. Performer (Choromanski et al., 2020) employs positive orthogonal random features to approximate attention kernels. The most relevant work, Sparse Transformer (Child et al., 2019), introduces sparsity to reduce KV cache memory footprint and achieve an efficient attention mechanism, considered as our baseline in this paper.

Caching. Caching, which plays a pivotal role in optimizing system performance, entails the development of effective eviction policies to handle frequently accessed data. Conventional approaches such as Least Recently Used and Least Frequently Used (O’neil et al., 1993; Lee et al., 2001) prioritize the recency and frequency of data access. And the design of KV cache encounters many similar challenges as traditional caching, *e.g.*, determining an appropriate cache size or devising optimal policies for expiration and eviction.

LLM Inference Breakdown. The generative procedure of LLMs encompasses two distinct phases: (i) the *prompt* phase, in which an input sequence is utilized to produce the KV cache (consisting of the key and value embeddings), similar to the forward pass employed during LLM training; and (ii) the *token generation* phase, which leverages and updates the KV cache to generate new tokens incrementally. Each generation step relies on the previously generated tokens. The primary focus of this paper is to enhance the efficiency of the KV cache in attention during the token generation phase, thereby accelerating LLM inference.

B.2. Discussions and Limitations

Previous Attempts. During our experiments, we find several noteworthy observations. In H₂O, employing the accumulated attention score to evict KV embeddings can lead to a potential bias favoring the least recent tokens. This bias arises because most previous tokens have a higher number of attention scores, resulting in a higher accumulated attention score and, consequently, a greater likelihood of being retained. To address this concern, we conducted an additional experiment utilizing the averaged attention score to determine which KV embeddings should be retained. However, this alternative approach resulted in performance degradation. Additionally, we observed a significant proportion of H₂ occurrences at the beginning of sentences. This finding suggests that the initial tokens play a substantial role in subsequent generation tasks.

Social Impact. Our work represents an initial effort in designing a KV Cache policy, a realm that has been relatively unexplored and yet is a significant bottleneck in LLMs. The proposed Heavy Hitter Oracle (H₂O) provide a solution to improve the efficiency of LLM generation, which can save energy cost and contribute to green AI. Besides, our approach also serves as a source of inspiration for future advanced algorithm designs. We envision H₂O as a foundational framework that could facilitate further innovation in this area. Moreover, long content generation is an area of growing importance that currently grapples with several efficiency issues. We hope our work that supports the generation of very long sequences will support further research in this direction, particularly in terms of enhancing consistency, devising superior evaluation methods, and establishing robust benchmarks.

Furthermore, another contribution of this study is the formulation of a dynamic submodular framework. We believe that this theoretical framework possesses the potential to be applicable beyond specific domains of interest. For instance, there may exist numerous other dynamic problems where the task involves solving a submodular problem with slight variations at each time.

Limitations. Furthermore, despite the notable advancements in throughput of our H₂O, implementing LLMs for generative inference remains challenging due to the immense parameter count. As a substantial portion of these parameters is encompassed within the MLP blocks, building upon our observations of H₂ occurrences in the MLP blocks, future research efforts can be directed towards leveraging the characteristics of H₂ to devise an offloading policy. Such a policy can potentially enhance the efficiency of LLM inference even further.

C. More Observations Details and Analysis

In this section, we present more details about two key empirical observations for Section 3.

C.1. Sparsity for Small Cache Size

We first show an observation on the sparsity of attention in pre-trained LLMs. Then we discuss how it can potentially unlock the possibility of reducing KV cache size without an accuracy drop. Given the normalized attention score $\text{Softmax}(QK^\top)$ matrix that is calculated by the query matrix Q and the key matrix K , we set the threshold as one percent of the maximum value in each row and calculates the corresponding sparsity.

Observation. We conduct zero-shot inference with the pre-trained OPT model on the validation set of Wiki-Text-103. We plot the layer-wise sparsity within attention blocks and visualize the normalized attention score matrix. The results are presented in Figure 2 (a). We observe that although the LLMs are densely trained, the resulting attention score matrices are highly sparse, with a sparsity over 95% in almost all layers.

Insights. The attention blocks’ sparsity suggests that access to all previous key and value embeddings is unnecessary for generating the next token. This suggests it is possible to evict unessential KV embeddings and reduce the requirement of KV cache during generation.

C.2. Heavy-Hitters for Low Miss Rate

The previous section showed that the sparse nature of attention blocks in pre-trained LLMs, which provides the opportunity for designing small KV cache size while still maintaining the performance of LLMs. However, determining the best eviction policy that preserves generation accuracy presents a combinatorial challenge. Although Belady’s Algorithm (Belady, 1966) is optimal and easy to compute for standard cache (offline), it is not applicable for KV cache design. Because once evicting important KVs, it could destroy the performance of LLMs due to the sequential dependency of LLM generation.

Observation. Fortunately, in the early stage of our exploration, we find that the accumulated attention scores of all the tokens within attention blocks follow a power-law distribution, as shown in Figure 2. This suggests the existence of a small set of tokens that are critical during generation. We denote those tokens as heavy-hitters (H_2). In order to verify the importance of these tokens, we compare the quality of LLM generation after masking heavy hitters with that of the original model. Not surprisingly, as shown in Figure 2, the accuracy drops drastically, confirming the importance of those tokens. Additionally, we can see the accumulated attention score of each word (in red dots) have high correlation with their co-occurrences in the data (gray curve).

Analysis. First, based on H_2 , we see an opportunity to side-step from the combinatorial search problem and design a KV cache eviction policy that preserves the LLM generation quality. We conduct an empirical study implementing a KV cache eviction policy that retains only the H_2 and the recent KV embeddings in the cache. The intuition is that recent words typically exhibit stronger correlations with current tokens. We assess the effectiveness of this eviction policy through pre-trained OPT-30B and six downstream tasks. The outcomes of these evaluations are illustrated in Figure 2. It is obvious that the H_2 based eviction policy can largely reduce the KV cache size without degrading the performance of OPT-30B.

Moreover, during the post analysis, inspired by (Han et al., 2019a), we find that H_2 based policy is related to the classical greedy algorithm (a polynomial-time algorithm with provable guarantees) under the assumption that the attention scheme is submodular. We present details in Appendix F.

Lemma C.1 (informal). Assuming the attention scheme is submodular, then greedily constructing the set S_i (without cache size limitation) satisfies the near-optimal property in terms of submodular.

D. An Example of Heavy-Hitter Eviction Algorithm

In this section, we choose a particular instantiation of the function F_{score} , i.e., the summation of that sets in the attention matrix, and describe an illustrative example of our algorithm (Algorithm 1) for Section 4

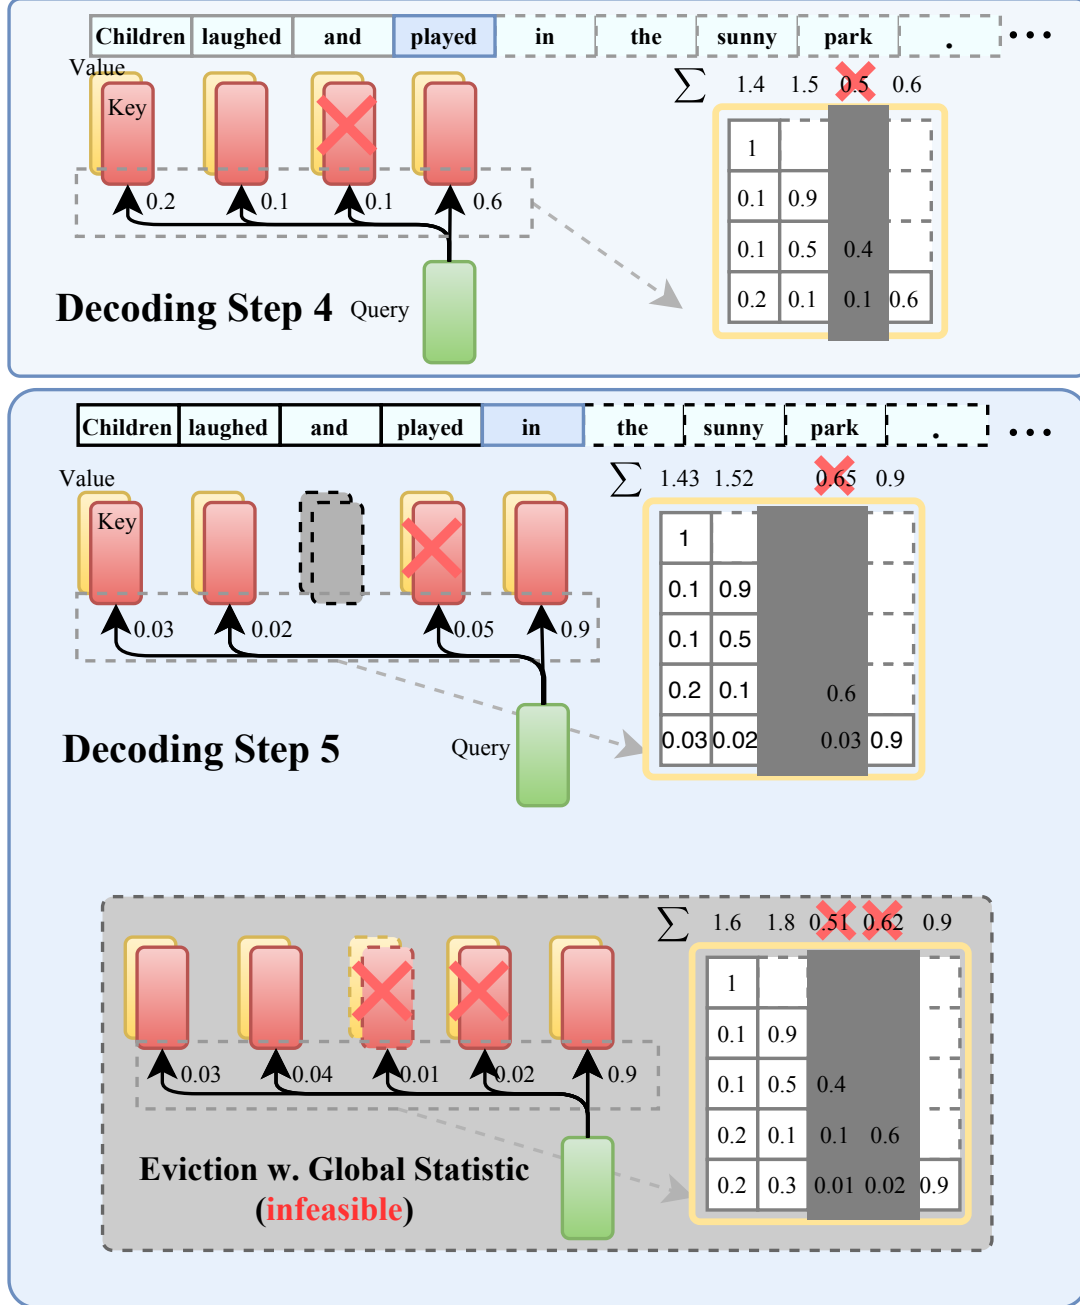

Figure 3: Illustration of Algorithm 1 during two consecutive decoding steps.

Figure 3 presents an illustrative example of our H_2 Eviction Algorithm. We assume that the budget size of KV cache is 3. Following the completion of the fourth decoding step, the KV embeddings associated with the third token are evicted based on the accumulated attention score. Consequently, these evicted KV embeddings become inaccessible in the subsequent decoding steps.

E. Complete Experiment Results

In this section, we present complete results for Section 5. Specifically, our goal is to demonstrate that H₂O, a remarkably simple KV cache eviction policy is capable of enhancing end-to-end throughput and reducing latency in wall-clock while maintaining generation quality across a broad spectrum of domains and tasks.

- In Section E.1, we show that H₂O can reduce the memory footprint of KV cache by up to $5\times$ without accuracy degradation on a wide range of model architectures (OPT, LLaMA, GPT-NeoX), sizes (from 6.7B to 175B) and evaluation benchmarks (HELM and lm-eval-harness). More importantly, can enhance the performance of existing KV cache sparsification techniques.
- In Section E.2, we demonstrate that H₂O can increase the inference throughput by up to $3\times$, $29\times$, $29\times$ compared to the state-of-the-art inference engine FlexGen, DeepSpeed and the widely used Hugging Face Accelerate without compromising model quality.
- In Section E.3, we present extensive ablation studies to show the effectiveness of H₂O under different sequence lengths, and its compatibility with quantization.

Additional investigations about H₂ are reported in Section E.4, E.5 and E.6, including (i) H₂O can also enhance the "Top-K" baseline; (ii) extra results of H₂ in attention blocks; (iii) the emergence of H₂ in MLP blocks as well as its properties.

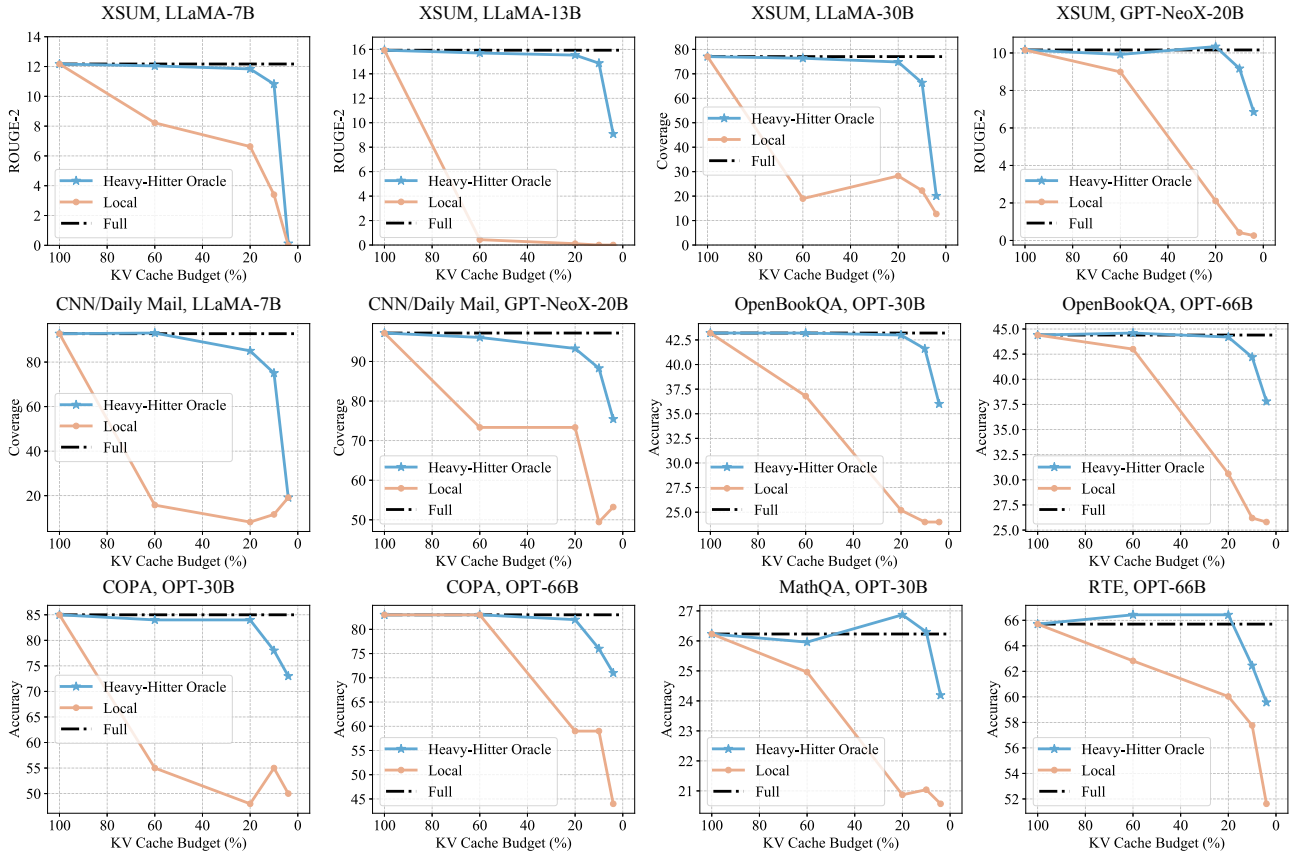

Figure 4: Comparison results between the baseline model with full cache, our H₂O, and the "Local" strategy that utilizes the most recent KV embeddings.

E.1. End-to-End Results

We demonstrate that H₂O can reduce KV cache memory footprint by $5\text{-}10\times$ while achieving comparable accuracy on a majority of tasks.

Setup. Our experiments are based on three representative model families of LLMs, including the OPT (Zhang et al., 2022) with model sizes ranging from 6.7 billion to 175 billion, LLaMA (Touvron et al., 2023), and GPT-NeoX-20B (Black et al., 2022). We sample eight tasks from two popular evaluation frameworks (HELM (Liang et al., 2022) and lm-eval-harness (Gao et al., 2021)): COPA (Roemmele et al., 2011), MathQA (Amini et al., 2019), OpenBookQA (Mihaylov et al., 2018), PiQA (Bisk et al., 2020), RTE (Wang et al., 2018), Winogrande (Sakaguchi et al., 2021), XSUM (Narayan et al., 2018), CNN/Daily Mail (Nallapati et al., 2016). We use NVIDIA A100 80GB GPU.

Baselines. Since H_2O evenly assigns the caching budget to H_2 and the most recent KV, except for full KV cache, we consider the "Local" strategy as a baseline method. Additionally, we also provide two different variants of Sparse Transformers (strided and fixed) as strong baselines.

Main Results. We evaluate LLMs with KV cache budget ranging from 4% to 100% on 5-shot downstream tasks. Results are summarized in Figure 4 and Table 1. The following observations can be drawn: (1) With different KV cache budgets, our H_2O demonstrates consistent and significant improvements against the "Local" strategy across various model sizes, model types, and downstream tasks. We can draw similar conclusions comparing H_2O with other baselines like Sparse Transformer. Meanwhile, with less than 20% KV cache budget (*i.e.*, more than $5\times$ memory reduction), H_2O achieves comparable performance as the model with full KV embeddings. Our H_2O shows consistent effectiveness in the more challenging long sequence generation tasks, XSUM, and CNN/Daily Mail.

Table 1: Results of different sparsification methods w. or w.o. H_2 . Experiments are conducted with OPT-30B with 20% KV cache budget.

Models	COPA	OpenBookQA	PiQA	Winogrande
Full	85.00	43.20	78.51	70.24
Local w.o. H_2	48.00	25.20	55.82	49.17
Local w. H_2	84.00	43.00	78.45	69.06
Sparse Transformer (strided) w.o. H_2	50.00	24.60	56.20	47.59
Sparse Transformer (strided) w. H_2	83.00	42.60	78.24	69.61
Sparse Transformer (fixed) w.o. H_2	61.00	23.80	58.60	49.88
Sparse Transformer (fixed) w. H_2	76.00	41.40	77.80	64.96

Analysis. Since the evicted KV will not be seen in the future steps, dropping certain critical KV embeddings can cause a severe functional collapse, resulting in significant performance degradation, *e.g.*, in {LLaMA-13B, XSUM} {LLaMA-7B, CNN/Daily Mail}, the "Local" strategy collapses at 60% budgets while our H_2O can still match the full cache performance with 20% budgets. In some tasks, our methods even surpass the baseline models, which demonstrates a regularization effect of our H_2O . For example, in {OPT-66B, RTE}, {OPT-30B, MathQA} and {GPT-NeoX-20B, XSUM}, our H_2O achieves an extra performance improvement of 0.73%, 0.64% and 0.18 with 20% KV cache budget, respectively. These consistent results validate the effectiveness of our H_2O framework.

Enhancing Baseline Techniques. Importantly, we observe other sparsification baselines fail under an extremely low cache budget while combining the most recent KV embeddings with the ones of heavy hitters successfully achieves comparable performance as using full KV embeddings. From Table 1, we can observe that both "strided" and "fixed" sparse attention fail under 20% KV cache budgets, encountering a significant performance drop (up to 35% compared with the full cache). After combining with H_2 , both approaches reach a similar performance as using full KV embeddings.

E.2. Heavy Hitter for High-Throughput Generative Inference

We implement our KV cache eviction policy in a state-of-the-art inference engine, FlexGen (Sheng et al., 2023), and report the throughput and latency improvements. H_2O is orthogonal to existing optimizations in FlexGen, such as offloading and quantization, so they can be combined to achieve better performance.

Table 2: Generation throughput (token/s) on a T4 GPU with different systems. In the sequence length row, we use "512 + 32" to denote a prompt length of 512 and a generation length of 32. "OOM" means out-of-memory. The gray text in the bracket denotes the effective batch size and the lowest level of the memory hierarchy that the system needs for offloading, where "C" means CPU and "G" means GPU.

Seq. length	512+32		512+512		512+1024	
	6.7B	30B	6.7B	30B	6.7B	30B
Accelerate	20.4 (2, G)	0.6 (8, C)	15.5 (1, G)	0.6 (8, C)	5.6 (16, C)	0.6 (8, C)
DeepSpeed	10.2 (16, C)	0.6 (4, C)	9.6 (16, C)	0.6 (4, C)	10.1 (16, C)	0.6 (4, C)
FlexGen	20.2 (2, G)	8.1 (144, C)	16.8 (1, G)	8.5 (80, C)	16.9 (1, G)	7.1 (48, C)
H_2O (20%)	35.1 (4, G)	12.7 (728, C)	51.7 (4, G)	18.83 (416, C)	52.1 (4, G)	13.82 (264, C)

Setup We conducted experiments on two GPUs: an NVIDIA T4 (16GB) GPU and an NVIDIA A100 (80GB) GPU. On the T4 GPU, we evaluate the generation throughput following the settings in the FlexGen paper. The evaluated models are OPT-6.7B and OPT-30B. When

the model and KV cache do not fit into a single GPU, we turn on CPU offloading. We use synthetic datasets where all prompts are padded to the same length. The system is then required to generate the same number of tokens for each prompt. We test different combinations of prompt and generation lengths. The evaluation metric is generation throughput, which is the number of generated tokens / (prompt time + decoding time). We use DeepSpeed ZeRO-Inference (Aminabadi et al., 2022), Hugging Face Accelerate (HuggingFace), and FlexGen (Sheng et al., 2023) as baselines. On the A100 GPU, with more GPU memory, we evaluate the performance of the systems with sequence lengths up to 10K. Although OPT is only trained on 2K sequence length, we benchmark the throughput and latency performance to show the potential of H₂O for better models in the future.

Table 3: Generation throughput and latency on an A100 GPU. In the sequence length row, we use “7000 + 1024” to denote a prompt length of 7000 and a generation length of 1024. “OOM” means out-of-memory.

Seq. length	Model size	Batch size	Metric	FlexGen	H ₂ O (20%)
7000+1024	30B	1	latency (s)	57.0	50.4
5000+5000	13B	4	latency (s)	214.2	155.4
2048+2048	6.7B	24	latency (s)	99.5	53.5
2048+2048	6.7B	24	throughput (token/s)	494.1	918.9
2048+2048	6.7B	64	throughput (token/s)	OOM	1161.0

Results. Table 2 shows the generation throughput of all systems on the T4 GPU. With our KV cache eviction policy, the memory usage is reduced, which brings two advantages: 1) we can use a much larger batch size; 2) we can make a setting from requiring offloading to not requiring offloading. As shown in Table 2, H₂O with a 20% budget improves the generation throughput over FlexGen, DeepSpeed, and Accelerate by up to 3 \times , 29 \times , and 29 \times , respectively. The results on the A100 GPU with sequence lengths from 4K to 10K are listed in Table 3. With the same batch size, H₂O can reduce the latency by 1.1 – 1.9 \times compared to FlexGen. Additionally, H₂O saves memory so it allows a larger batch size, which brings 2.3 \times improvement on generation throughput for OPT-6.7B.

E.3. Ablation Results

We present extensive ablation studies of H₂O on (1) different sequence length, (2) compatibility with quantization methods on KV cache, and (3) dissecting the effectiveness of different components. Moreover, we find a surprising property of H₂O – it not only improves efficiency of LLMs, but also increases diversity of the generated text.

Q1: Does the number of shots during inference effects the effectiveness of H₂O? A1: Effective under both 5 and 10 shots inference. We further examine H₂O under different numbers of shots during inference, and the results are reported in Table 4. Both with 5 and 10

shots inference, our H₂O achieves matching performance (difference less than 1.00%) as the full model across different downstream tasks. And the "Local" strategy encounters significant performance degradation (up to 37.00%). Such results demonstrate the effectiveness of our H₂O under different inference scenarios.

Q2: Compatible with Quatization? A2: Yes. To pursue further efficiency, we show the compatibility of H₂O with another orthogonal approach, *i.e.*, quantization in Table 5. We use OPT-30B as our base model and COPA, OpenBookWA, and PiQA as evaluation tasks. Intuitively sparsity and quantization are highly related, so combining them might introduce larger errors. Surprisingly the combination almost always achieves better accuracy than H₂O or quantization alone.

To further explore the compatibility of our H₂O with quantization with

Table 4: Results under different sequence length of OPT-30B with 20% KV cache budget.

Tasks	Methods	5-shots		10-shots

Quant-4bit	84.00	43.28	78.67
H ₂ O w. Quant-4bit	84.00	43.20	78.80

respect to throughput improvement, we conduct an additional evaluation with the quantization method implemented in FlexGen (Note that (Dettmers & Zettlemoyer, 2022) employed a different 4-bit quantization method). The corresponding results are presented in Table 7. Notably, for OPT-6.7B, we observed extra performance enhancements in H₂O when utilizing quantization compared to the vanilla version. This improvement results from the GPU memory freed by weight quantization, which allows for a significant increase in batch size. However, it should be emphasized that the quantization method employed in FlexGen is not implemented most efficiently, resulting in considerable computational overhead. Despite the batch size being enlarged by 20 times, the actual throughput improvement is less than 2 times. Nevertheless, it is important to acknowledge the potential benefits of combining H₂O with quantization, as exemplified by the ability to increase the batch size further. For instance, the implementation of 4-bit quantization could be accelerated by an optimized CUDA kernel.

Q3: When does H₂O match the baseline with full KV embeddings? A3: With both H₂ and the recent tokens. We investigate the separate effects of KV embeddings of H₂ and the local tokens. We conduct experiments on 4 tasks with OPT-13B and OPT-30B. For each task, we compare the performance of three KV cache eviction policies, including only the KV embeddings of H₂, only the ones of local tokens, and our H₂O that keep both. As shown in Table 6, only retaining the embeddings of H₂ or local tokens can’t maintain a similar performance as the model using full embeddings, with a performance degradation from 2.85% to 22.75%. Incorporating both components, our H₂O successfully retains the baseline performance with full embeddings. Besides, the model with only H₂ shows a consistent improvement against the one with only local tokens, which indicates that H₂ might contribute more to maintaining the performance of networks.

Q4: Extra benefits from H₂O? A4: Increased diversity of generated text.

Besides all the benefits of our H₂O, we also observe an bonus introduced by H₂O, *i.e.*, the improved diversity of generated content. Given the same prompt text, we visualize the generated text with OPT-6.7B and LLaMA-7B across different methods, including the baseline model with full cache, our H₂O, and the "Local" strategy. Results are reported in Figure 5 and 6. Even with less KV cache budget, our H₂O can generate more diverse content. Specifically, with the OPT-6.7B, the full model generates some redundant works, like "a few years after the events of the first game" while our H₂O describes "the game is a first-person exploration game". As a comparison, when all KV cache budget is assigned to the most recent tokens, the model fails to generate meaningful text and only repeats the word "." and ",". Similar observations can also be drawn from the results of LLaMA-7B, in which the full model repeatedly says "so moving that", "so moved that", and "began to cry" while our H₂O describes both the people and the environment.

Table 7: Generation throughput (token/s) with different systems without offloading. We use H₂O-c denotes the H₂O with 4-bit weights compression. In the sequence length row, we use "512 + 32" to denote a prompt length of 512 and a generation length of 32. "OOM" means out-of-memory. The gray text in the bracket denotes the batch size. We run OPT-6.7B on a single T4 GPU.

Seq. length	512+32	512+512	512+1024
Model size	6.7B	6.7B	6.7B
Accelerate	20.4 (2)	15.5 (1)	OOM
DeepSpeed	OOM	OOM	OOM
FlexGen	20.2 (2)	16.8 (1)	16.9 (1)
H ₂ O (20%)	35.1 (4)	51.7 (4)	52.1 (4)
H ₂ O-c (20%)	57.2 (80)	72.5 (52)	62.3 (44)

Table 6: Ablation study of H₂O across different tasks.

Tasks	Models	Full	w. Local	w. H ₂	w. Local + H ₂
PiQA	OPT-13B	77.37	54.62	76.12	77.26
	OPT-30B	78.51	55.82	67.25	78.45
OpenBookQA	OPT-13B	41.40	25.60	30.40	41.20

Winogrande	OPT-13B	68.59	49.96	51.85	67.32
	OPT-30B	70.24	49.17	47.36	69.06

E.4. Enhancing the "Top-K" Baseline

We find H₂ can further enhance another strong baseline with a "Top-K" strategy. The results are reported in Table 8. After combining with H₂, the "Top-K" method achieves an extra improvement with up to 2.00% accuracy across 4 different tasks.

E.5. Heavy-Hitter in Attention Blocks

The distribution of accumulated attention scores of all the tokens within attentions blocks is illustrated in Figure 7. We can observe that H₂ broadly exists in each layer.

Table 8: Results of the "Top-K" method *w.* or *w.o.* H₂. Experiments are conducted with OPT-30B with 20% KV cache budget.

Models	COPA	OpenBookQA	PiQA	Winogrande
Full	85.00	43.20	78.51	70.24
TopK <i>w.o.</i> H ₂	80.00	41.40	76.96	65.35
TopK <i>w.</i> H ₂	82.00	42.80	77.96	66.48

Besides the attention blocks, the presence of Heavy-Hitters (H_2) is observed within the MLP blocks of LLMs. We utilize the Wiki-Text-103 dataset as the input and record the activated frequency of neurons in the hidden layer of MLP blocks. As depicted in Figure 8, the activated frequency of neurons follows a power-law distribution, wherein a small number of neurons are activated by nearly all input tokens (with a 100% frequency) while the majority of other neurons are rarely activated.

19

Model Input

In a small, bustling cafe nestled in the heart of a vibrant city, a serendipitous event unfolded, leaving a lasting impression on all who witnessed it. As the patrons sat sipping their coffees and engaging in animated conversations, a talented street musician entered the cafe, carrying a weathered guitar and radiating an aura of creativity.

LLaMA-7B Full Cache Output

He began to play, and the patrons were captivated. The musician’s performance was so moving that the patrons began to applaud, and the musician was so moved that he began to cry. The patrons were so moved that they began to cry, and the musician was so

characteristic, and their positions undergo gradual changes during subsequent training phases.

Elimination of H₂. We first train a GPT-2 using Wiki-Text-103 dataset and subsequently identify and prune the neurons exhibiting an activation frequency exceeding 20% (*i.e.*, H₂). This pruning operation leads to a substantial decline in performance, as evidenced by an increase in perplexity from 19.32 to 31.78. The results emphasize the criticality of H₂ in preserving the functionality of the model. To assess the recoverability of the discarded information, we conduct a few-shot fine-tuning experiment, and the results are summarized in Table 9. The pruned model is fine-tuned with varying ratios of training data for 500 iterations, and it successfully regains performance levels equivalent to those of the pre-trained model. In contrast, when training the model from scratch using only 1% of the training data, the resulting model achieves a perplexity of 554.12 only. These findings demonstrate that the knowledge encoded in H₂ can be easily restored.

Table 9: . Perplexity on the test-set of Wiki-Text-3 with GPT-2.

Settings	1%	10%	40%	100%
Pretrained Model		19.32		
Remove H ₂		31.78		
Fine-tuning	19.86	19.84	19.76	19.83

Overlap across Diverse Input Contents. Moreover, we conduct a comparative analysis of the activation frequencies acquired from various input contents. Specifically, utilizing the pretrained OPT-1.3B model, we evaluate three datasets, namely Wiki-Text-103, Penn Treebank, and Amazon Review. The positioning of H₂ is depicted in Figure 9, revealing significant concurrence across multiple datasets.

Early-Bird Property. Furthermore, our investigation reveals that H₂ displays an "early-bird" characteristic, as illustrated in Figure 10. By visualizing the distribution of activation frequencies across various checkpoints throughout the training process,

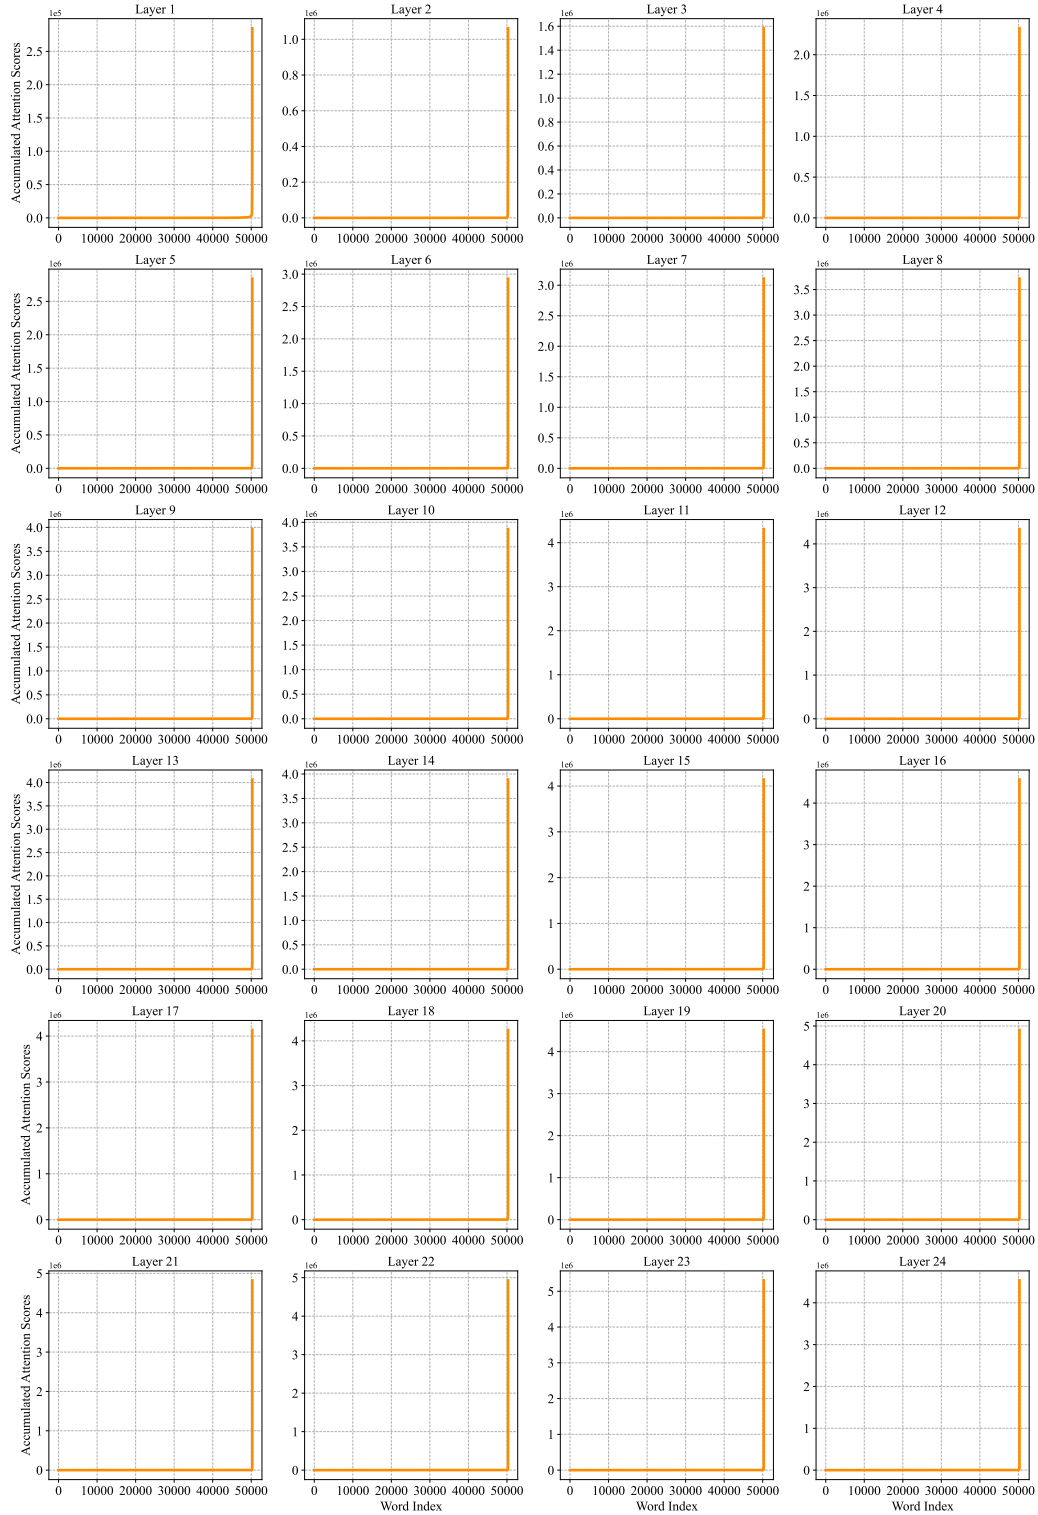

Figure 7: The distribution of accumulated attention scores with respect to the corresponding word. The x-axis represents the word index in the vocabulary, and the y-axis represents the accumulated attention score. Results are obtained from OPT-1.3B.

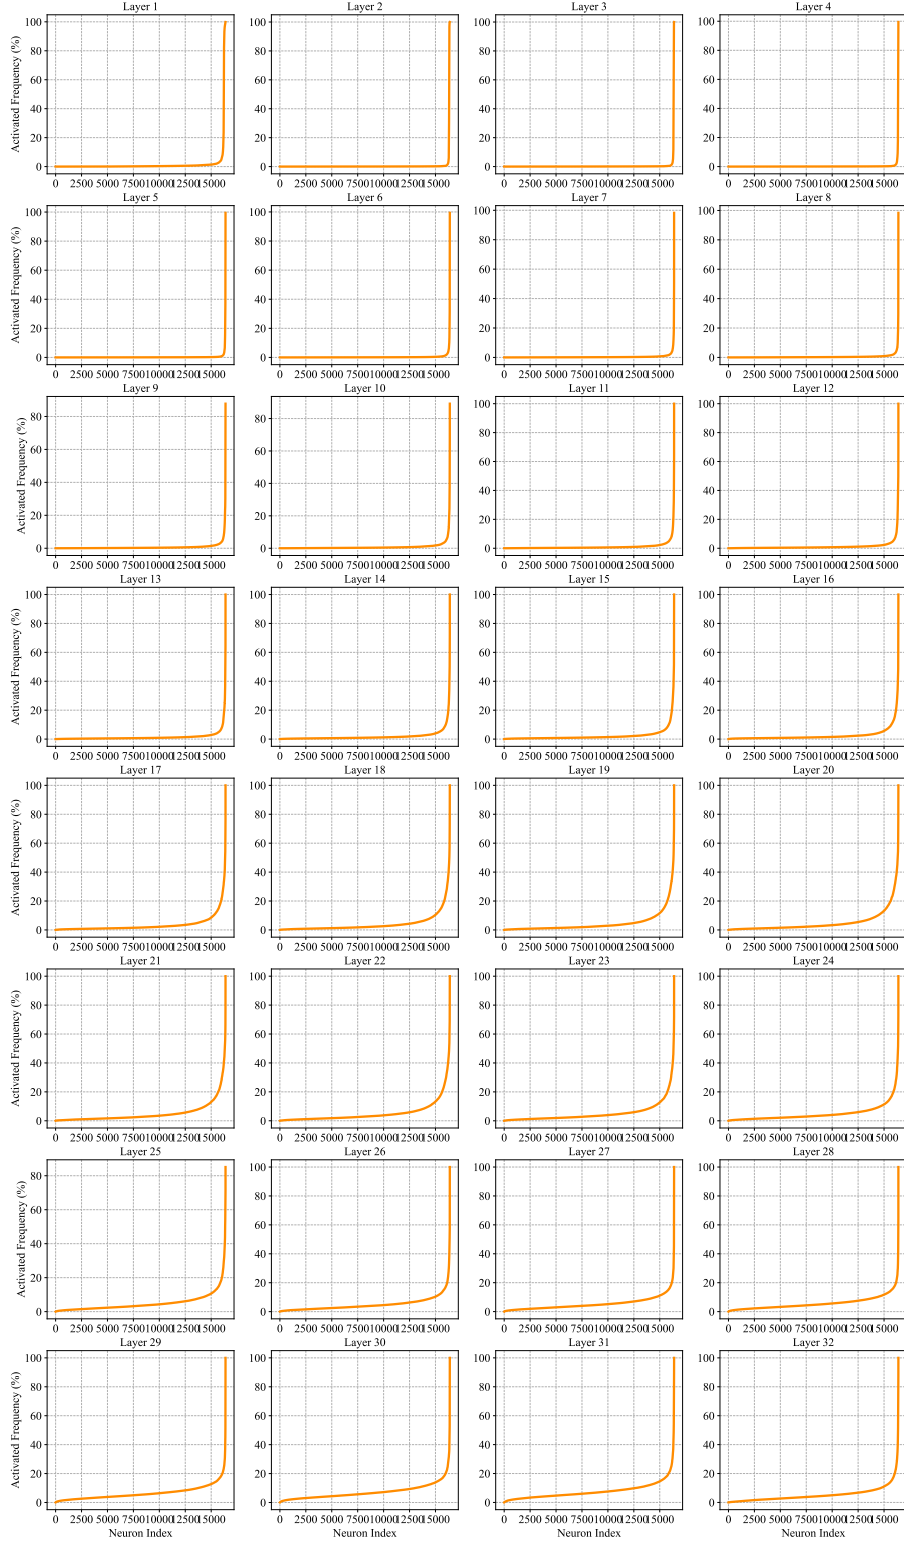

Figure 8: The emergence of H_2 in MLP blocks of OPT-6.7B. The x-axis represents the index of neurons in the hidden layers of MLP blocks, and the y-axis represents the activated frequency.

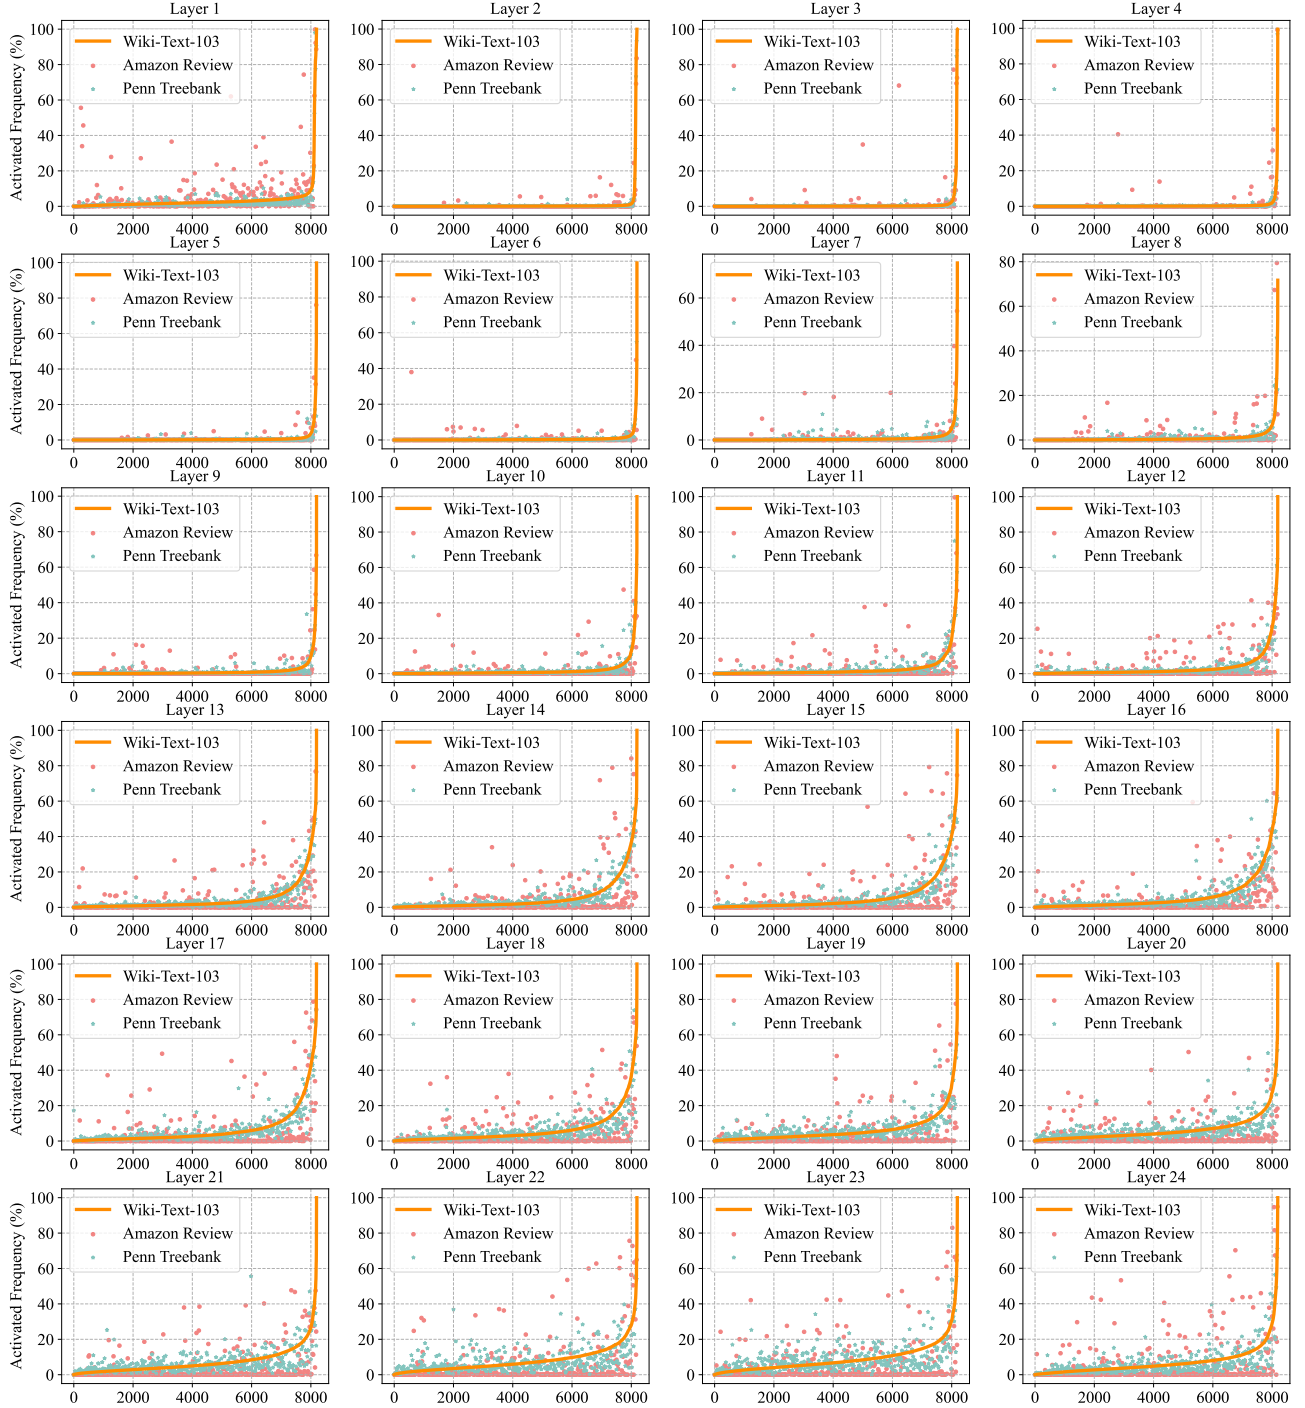

Figure 9: The distribution of activated frequency across diverse input content. The x-axis represents the index of neurons, which is ordered by the activated frequency from Wiki-Text-103.

we observe the emergence of a power-law behavior at an initial stage, specifically as early as a training budget of 4%. Subsequently, the positions of H_2 exhibit gradual and minimal changes.

F. Theoretical Analysis

Recently, a number of works have studied the attention scheme in LLMs from a theoretical perspective (Zandieh et al., 2023; Alman & Song, 2023; Brand et al., 2023; Gao et al., 2023a; Deng et al., 2023b; Li et al., 2023b; Deng et al., 2023a; Gao et al., 2023b; Sinha et al., 2023). In this work, we provide a different and novel angle compared to the previous work. We present the concept of the submodular property and propose an eviction policy, known as greedy H_2 , which is a modification of dynamic submodular maximization. Furthermore, assuming the attention scheme to be submodular, we establish that constructing the set S_i without any cache size limitation satisfies the near-optimal property in terms of submodularity. We provide theoretical guarantees for our robust and approximate greedy eviction policy algorithm (Algorithm 2). Due to space limitation, we only give informal description of algorithm (Algorithm 2) in Section 4.1. In Section F.6, we give an algorithm (Algorithm 2) which has full and complete implementation details for Algorithm 1. We also offer a mathematical formulation for sparsity preservation that is observed in Section 3 and proposed an algorithm (Algorithm 4) to solve the problem.

Specifically, in Section F.1, we provide several basic definitions and notations. In Section F.2, we briefly the definition of submodular function. In Section F.3, we define the dynamic submodular framework, which gives the formal version of Definition 4.1. In Section F.4, we briefly review the static attention computation problem. In Section F.5, we formulate the attention computation in recursive fashion. In Section F.6, we briefly review our eviction policy, which gives the formal version of Definition 4.3. In Section F.7, we discuss the diminishing return for submodular. In Section F.8, we discuss the high-level ideas for submodular. In Section F.9, we analyze the robust greedy algorithm error propagation. In Section F.10, we explain how to add items into sets via approximate function. In Section F.11, we provide several definitions related to dynamic properties. In Section F.12, we prove an induction lemma for the exact function. In Section F.13, we prove an induction lemma for the approximation function. In Section F.14, we provide theoretical guarantees for both the full-knowledge version (formal version of Lemma 3.1) and the limited-cache-size version (formal version of Theorem 4.4). In Section F.15, we provide a more detailed discussion of theoretical work about attention computation and regression-related problems. In Section F.16, we provide a mathematical formulation for sparsity preserving. In Section F.17, we provide the definition of loss function which can potentially generate sparse (heavy hitter type attention sore). In Section F.18, we explain how to compute the gradient of the loss function. In Section F.19, we show how to compute the Hessian of the loss function. In Section F.20, we show that Hessian is positive definite. In Section F.21, we prove the Lipschitz property for the Hessian matrix. In Section F.22, we show that using a gradient-type algorithm is sufficient to optimize that (heavy hitter type) loss function.

F.1. Notations

For a positive integer n , let $[n] := \{1, 2, \dots, n\}$.

For a vector $x \in \mathbb{R}^n$, let $\sqrt{x} \in \mathbb{R}^n$ denote the vector with the i -th entry being $\sqrt{x_i}$ and $\text{diag}(x) \in \mathbb{R}^{n \times n}$ denote the diagonal matrix with the i -th diagonal entry being x_i . For two matrices $A, W \in \mathbb{R}^{n \times n}$, let $\|A\|_W := (\sum_{i=1}^n \sum_{j=1}^n W_{i,j} A_{i,j}^2)^{1/2}$ and $W \circ A$ denote the matrix where $(W \circ A)_{i,j} = W_{i,j} A_{i,j}$. For matrix $W \in \mathbb{R}^{n \times n}$, let $D_{W_i} := \text{diag}(W_{i,:})$ with $i \in [n]$.

For two vectors $x \in \mathbb{R}^n$ and $w \in \mathbb{R}_{\geq 0}^n$, let $\|x\|_w := (\sum_{i=1}^n w_i x_i^2)^{1/2}$. For a vector x , its ℓ_2 norm is defined as $\|x\|_2 := (\sum_{i=1}^n x_i^2)^{1/2}$ and its ℓ_p norm is defined as $\|x\|_p := (\sum_{i=1}^n |x_i|^p)^{1/p}$. For a square matrix A , we denote $\text{tr}[A]$ as the trace of matrix A .

For a matrix $A \in \mathbb{R}^{n \times k}$ (suppose $n \geq k$), we use $\|A\|$ to denote its spectral norm, i.e., $\|A\| = \sup_x \|Ax\|_2 / \|x\|_2$. We use $\|A\|_F$ to denote its Frobenius norm $\|A\|_F := (\sum_{i=1}^n \sum_{j=1}^k A_{i,j}^2)^{1/2}$.

Suppose matrix $A \in \mathbb{R}^{n \times k}$ has SVD decomposition $U\Sigma V^\top$ where $U \in \mathbb{R}^{n \times k}$ (this matrix has orthonormal columns), $\Sigma \in \mathbb{R}^{k \times k}$ is a diagonal matrix, and $V \in \mathbb{R}^{k \times k}$. We call columns of U singular vectors. We use $A^\dagger \in \mathbb{R}^{k \times n}$ to denote the Moore-Penrose pseudoinverse, then $A^\dagger = V\Sigma^{-1}U^\top$. Suppose $\Sigma \in \mathbb{R}^{k \times k}$ is sorted diagonal matrix, let $\sigma_1, \dots, \sigma_k$ denote the diagonal entries of Σ . Then we call σ_i the i -th singular value of the matrix, and we write it as $\sigma_i(A)$.

For any symmetric matrix $B \in \mathbb{R}^{k \times k}$, we denote its eigenvalue decomposition as $U\Lambda U^\top$, where Λ is a diagonal matrix. Let $\lambda_1, \dots, \lambda_k$ denote the entries on diagonal of $\Lambda \in \mathbb{R}^{k \times k}$. We say λ_i is the i -th eigenvalue. Usually, we write it as $\lambda_i(B)$.

The connection between eigenvalues and singular values is

$$\sigma_i^2(A) = \lambda_i(A^\top A)$$

We use the notation $A \succeq 0$ to denote that matrix A is positive semidefinite (psd). Mathematically, $A \succeq 0$ means for all vectors x , we have $x^\top Ax \geq 0$.

Similarly, for two squarer matrices A and B , we use $A \succeq B$ to denote the case where for all vectors x , $x^\top Ax \geq x^\top Bx$.

Let $\Pr[\cdot]$ and $\mathbb{E}[\cdot]$ denote the probability and expectation. We define the maximum between a and b as $\max\{a, b\}$. We denote $\min\{a, b\}$ (resp. $\max\{a, b\}$) as the minimum (reps. maximum) between a and b .

Throughout, for non-negative real numbers a and b , we use the notation $a = (1 \pm \epsilon)b$ if $a \in [(1 - \epsilon)b, (1 + \epsilon)b]$.

F.2. Submodular

We provide the standard definition of the submodular function.

Definition F.1 (Submodular function (Schrijver, 2003)). For a finite set Ω , a submodular function is defined as $f : 2^\Omega \rightarrow \mathbb{R}$, where 2^Ω denotes the power set of Ω . It is characterized by the fulfillment of any of the following equivalent criteria:

- Condition 1.
 - For $S, T \subseteq \Omega$ with $S \subseteq T$ and every $a \in \Omega \setminus T$ we have that $f(S \cup \{a\}) - f(S) \geq f(T \cup \{a\}) - f(T)$
- Condition 2.
 - For every $S, T \subseteq \Omega$ we have that $f(S) + f(T) \geq f(S \cup T) + f(S \cap T)$.
- Condition 3.
 - For every $S \subseteq \Omega$ and $a_1, a_2 \in \Omega \setminus S$ such that $a_1 \neq a_2$ we have that $f(S \cup \{a_1\}) + f(S \cup \{a_2\}) \geq f(S \cup \{a_1, a_2\}) + f(S)$.

For convenience of discussion, in this paper, we always choose $\Omega = [n]$ when we want to discuss the submodular function.

Next, we provide some examples/types of submodular functions. One important class is called monotone,

Definition F.2 (Monotone). A set function f is monotone if for every $T \subseteq S$ we have $f(T) \leq f(S)$.

Here are a number of monotone submodular functions

- Linear (Modular) functions
 - A linear function can be represented as $f(S) = \sum_{i \in S} w_i$. If all the weights w_i are nonnegative, then the function f is considered monotone.
- Budget-additive functions
 - A budget-additive function has the form $f(S) = \min(B, \sum_{i \in S} w_i)$ where each weight w_i and the budget B are nonnegative.
- Coverage functions
 - We have a set $\Omega = \{E_1, E_2, \dots, E_n\}$ where each E_i is a subset of a broader set Ω' . The coverage function can be expressed as $f(S) = |\cup_{E_i \in S} E_i|$ for any $S \subset \Omega$. This function can be generalized by assigning non-negative weights to the elements.

F.3. Dynamic Submodular

The standard submodular function is mapping $2^{[n]}$ to real. Here we need a more general definition that maps $2^{[n]} \times 2^{[n]}$ to real.

Definition F.3 (Strong submodular). We define function $F : 2^{[n]} \times 2^{[n]} \rightarrow \mathbb{R}$, then for any set $Z \subset [n]$, we assume that $F(Z, \cdot) : 2^{[n]} \rightarrow \mathbb{R}$ is a submodular function.

In fact, the above definition is stronger than we want, what we really need can be written as follows. We remark that in Definition 4.1 we provide an informal definition. Here we provide a more detailed version of the definition.

Definition F.4 (Dynamic submodular framework, formal version of Definition 4.1). Define function

$$F : 2^{[n]} \times [n] \times 2^{[n]} \rightarrow \mathbb{R}.$$

Then for any index $i \in [n]$, any set $Z \subseteq [i-1]$, we assume that

$$F(Z, i, \cdot) : 2^{[n]} \rightarrow \mathbb{R}$$

is a submodular function w.r.t. to Z , i.e.,

- For all sets $X, Y \subset [n]$ satisfy that $Z \subset X \subset Y$,
- For all element $x \in [n]$ satisfy that $x \in [n] \setminus Y$,

we have

$$f_{Z,i}(X \cup \{x\}) - f_{Z,i}(X) \geq f_{Z,i}(Y \cup \{x\}) - f_{Z,i}(Y),$$

where $f_{Z,i}(\cdot) := F(Z, i, \cdot)$.

Remark F.5. We remark that Definition F.4 is a weaker version of Definition F.3. We also like to mention that the informal definition (see Definition 4.1) only contains two input parameters, but in fact we need three input parameters (see Definition F.4).

In the later, when we use $f_{Z,i}(\cdot)$, we will replace Z by S_i for convenient of analysis, for example see Definition F.23, Definition F.24, Definition F.25 and Definition F.26.

F.4. Static Attention

Before we describe the recursive attention computation, we will first describe the static version of attention computation as follows (for examples, see Definition 1.1 in (Alman & Song, 2023) and others (Zandieh et al., 2023; Brand et al., 2023; Gao et al., 2023a; Deng et al., 2023b)):

Definition F.6. Given three matrices $Q, K, V \in \mathbb{R}^{d \times d}$, the goal is to compute

$$\text{Att}(Q, K, V) := D^{-1} A \cdot V$$

where square matrix $A \in \mathbb{R}^{n \times n}$ can be rewritten as follows

$$A = \exp(QK^\top)$$

and diagonal matrix $D \in \mathbb{R}^{n \times n}$ can be written as follows

$$D = \text{diag}(A\mathbf{1}_n)$$

Here we apply $\exp()$ to a matrix entry-wisely to a matrix. $\mathbf{1}_n$ is a length- n vector where all the entries are ones. The operator $\text{diag}()$ is turning a vector into a diagonal matrix.

F.5. Recursive Attention Definition

We first provide some definitions.

Definition F.7. Given a query matrix $Q \in \mathbb{R}^{n \times d}$, we use $Q_{i,*}$ to denote a length- d row vector that represents the i -th row of Q for each $i \in [n]$.

Definition F.8. Given a key matrix $K \in \mathbb{R}^{n \times d}$, we use $K_{\leq i,*}$ to denote a $i \times d$ matrix that selects the first i rows from K .

Next, we show the exact version of computing attention.

Definition F.9 (Exact Version). Given $Q, K \in \mathbb{R}^{n \times d}$

- For each $i \in [n]$, we use $o_i \in \mathbb{R}^i$ to denote a length- i vector.

Figure 11: (a) Exact version of the attention computation. Here, our example is about the language modeling task. At this stage, the model predicts the word 'apple' and computes the exact attention vector o_4 . (b) Approximate version of the attention computation. Let the budget of the number of tokens we can track be 3. We truncate the key matrix for the first token $K_{1,*}$ and only keep $K_{2,*}$, $K_{3,*}$ and $K_{4,*}$ in the memory. Compared with the exact version, we don't compute $o_{4,1}$.

- For each $j \in [i]$, we use $o_{i,j}$ to denote the j -th coordinate of vector $o_i \in \mathbb{R}^i$

For the first layer, we have

- $o_{1,1} = 1$.

For the second layer, we have

- length-2 vector $o_2 := \underbrace{D_2^{-1}}_{\text{scalar}} \cdot \underbrace{\exp(Q_{2,*} (K_{\leq 2,*})^\top)}_{1 \times d \cdot d \times 2}$
- scalar $D_2 := \underbrace{\exp(Q_{2,*} (K_{\leq 2,*})^\top)}_{1 \times 2} \cdot \underbrace{\mathbf{1}_2}_{2 \times 1}$

For each $i \in [n]$, for the i -th layer, we have

- length- i vector $o_i := \underbrace{D_i^{-1}}_{\text{scalar}} \cdot \underbrace{\exp(Q_{i,*} (K_{\leq i,*})^\top)}_{1 \times d \cdot d \times i}$
- scalar $D_i := \underbrace{\exp(Q_{i,*} (K_{\leq i,*})^\top)}_{1 \times i} \cdot \underbrace{\mathbf{1}_i}_{i \times 1}$

Now, we show the approximate version of computing attention. Instead of computing the entire attention o_i , we only compute the attention of the tokens that are being tracked.

Definition F.10 (Approximate Version). Given $Q, K \in \mathbb{R}^{n \times d}$

- For each $i \in [n]$, we use $o_i \in \mathbb{R}^i$ to denote a length- i vector.
 - For each $j \in [i]$, we use $o_{i,j}$ to denote the j -th coordinate of vector $o_i \in \mathbb{R}^i$

- Let $k \in [n]$ be the budget of the number of tokens we can track (due to the memory issue).

For the first layer, we have

- $o_{1,1} = 1$.

For the second layer, we have

- length-2 vector $o_2 := \underbrace{D_2^{-1}}_{\text{scalar}} \cdot \exp(\underbrace{Q_{2,*}}_{1 \times d} \underbrace{(K_{\leq 2,*})^\top}_{d \times 2})$
- scalar $D_2 := \underbrace{\exp(Q_{2,*}(K_{\leq 2,*})^\top)}_{1 \times 2} \cdot \underbrace{\mathbf{1}_2}_{2 \times 1}$

For each $i \in [n]$, for the i -th token, we have

- Let $S_i \subset [n]$ denote the tokens we're tracking when we are predicting the i -th token.
- $|S_i| = k$
- $|S_i \setminus S_{i-1}| \leq 1$ or equivalently $|S_i \cap S_{i-1}| \geq k - 1$
- length- i vector $o_i := \underbrace{D_i^{-1}}_{\text{scalar}} \cdot \exp(\underbrace{Q_{i,*}}_{1 \times d} \underbrace{(K_{S_i,*})^\top}_{d \times i})$
- scalar $D_i := \underbrace{(\exp(Q_{i,*}(K_{S_i,*})^\top) - \mathbf{1}_{[i] \setminus S_i})}_{1 \times i} \cdot \underbrace{\mathbf{1}_i}_{i \times 1}$

In a certain sense, the above definition is related to finding heavy hitters in compressive sensing (for more background on compressive sensing, we refer readers to (Larsen et al., 2016; Nakos & Song, 2019; Nakos et al., 2019)).

F.6. Eviction Policy

The goal of this section is to our eviction policy under space limitation. We start by giving a process without having space limitations. We denote the attention query matrix as $Q \in \mathbb{R}^{n \times d}$ and the key matrix as $K \in \mathbb{R}^{n \times d}$. $Q_{i,*}$ represents the i -th row of Q and $K_{\leq i,*}$ represents the first i rows of K . For simplicity, $K_{S_i,*}$ denotes a sub-matrix of K which selects S_i rows from K .

Definition F.11 (The generative process with Full knowledge). For each $i \in [n]$, for the i -th token, we have

- length- i vector $o_i := D_i^{-1} \cdot \exp(Q_{i,*}(K_{\leq i,*})^\top)$, which denotes the attention of the i -th word.
- scalar $D_i := \exp(Q_{i,*}(K_{\leq i,*})^\top) \cdot \mathbf{1}_i$, which denotes the normalization factor.

In the above process, since we have no space limitation, then we can keep all the scores. In the following process, we show how to handle things when there is a space limitation. In this case, we need to dynamically maintain set S_i such that $|S_i| \leq k$ (Compared to the full knowledge case, we can think of $|S_i| = i$).

Definition F.12 (H₂O Eviction Policy, Formal version of Definition 4.3). Let k denote the budget of space and $k < n$. Let $F_{\text{score}} : 2^{[n]} \rightarrow \mathbb{R}$ denote certain score function. Let S_{i-1} denote the source set. Let S_i denote the target set. We defined the eviction policy $g : S_{i-1} \rightarrow S_i$ s.t.

- $|S_i| \leq k$ (KV cache size is not changing over the time)
- $|S_i \setminus S_{i-1}| \leq 1$ (we can evict at most 1 KV in the KV cache)
- We construct $S_i \leftarrow (S_{i-1} \cup \{i\}) \setminus \{u\}$ as $u \leftarrow \arg \max_{v \in (S_{i-1} \cup \{i\})} F_{\text{score}}(S_{i-1} \cup \{i\} \setminus \{v\})$

Algorithm 2 H₂ Eviction Algorithm, Query matrix $Q \in \mathbb{R}^{n \times d}$, key matrix $K \in \mathbb{R}^{n \times d}$, budget size of KV cache $k \in \mathbb{N}$. Formal and detailed version of Algorithm 1.

```

1: procedure H2_EVICTON( $Q \in \mathbb{R}^{n \times d}, K \in \mathbb{R}^{n \times d}, k \in \mathbb{N}$ )
2:    $S_0 \leftarrow \emptyset, \tilde{o}_0 \leftarrow 0$                                 ▷ Initialization the algorithm
3:   for  $i = 1 \rightarrow n$  do                                         ▷ Linear scan each token
4:     if  $i \leq k$  then                                           ▷ If the KV cache is not full
5:        $S_i \leftarrow S_{i-1} \cup \{i\}$                              ▷ Expand the set directly
6:     else                                                       ▷ If the KV cache is full
7:        $D_i \leftarrow (\exp(Q_{i,*}(K_{S_i,*})^\top) - \mathbf{1}_{[i] \setminus S_i}) \cdot \mathbf{1}_i$     ▷ Compute the normalization factor
8:        $o_i \leftarrow D_i^{-1} \cdot \exp(Q_{i,*}(K_{S_i,*})^\top)$         ▷ Compute score vector
9:        $\tilde{o}_i \leftarrow \tilde{o}_{i-1} + o_i$                             ▷ Accumulate the scores (Remark F.15)
10:      Let score function be  $F_{\text{score}}(T) := h(\sum_{s \in T} \tilde{o}_{i,s})$     ▷ Score function (Remark F.14)
11:       $u \leftarrow \arg \max_{v \in (S_{i-1} \cup \{i\}) \setminus \{v\}}$         ▷ Find an entry to swap
12:       $S_i \leftarrow (S_{i-1} \cup \{i\}) \setminus \{u\}$                 ▷ Construct  $S_i$ 
13:    end if
14:  end for
15: end procedure

```

Remark F.13. We remake that, in Definition 4.3, we introduce a simplified notation where we state that $|S_i| = k$ in the first bullet point, but in general, we consider the case where $|S_i| \leq k$ for the first k tokens. To accommodate this more general scenario, we present Definition F.12, which provides a broader definition that handles the situation where $|S_i| \leq k$.

Remark F.14. We remark the above function F_{score} can have multiple choices. In the later analysis, we provide two choices. If we use the exact function, then F_{score} is $f_{S_i,i}$ (see Definition F.23 and Definition F.25). If we use the approximate function, then F_{score} is $\tilde{f}_{S_i,i}$ (see Definition F.24 and Definition F.26). Let $h : \mathbb{R} \rightarrow \mathbb{R}$ (the h being used Line 10 in Algorithm 2) denote function. We hope to choose h such that it gives the submodular property for the function F_{score} in the sense of our dynamic framework. For example, $h(z)$ is usually chosen to be some non-decreasing concave function such as $\sqrt{z+1}$ and $\log(z+1)$. For simplicity, in Algorithm 1 (which is the informal version of Algorithm 2), we choose $h(z) = z$ for the purpose of providing readers with an intuitive understanding and due to space limitation.

Remark F.15. We remark that, in Line 10 in Algorithm 2, the $\tilde{o}_{i,s}$ is the accumulation of attention score for the token s in set T . In our Algorithm 1, we only use o_s in Line 10 (see Algorithm 1) to represent that accumulation of the attention score for simplicity.

In Algorithm 2, for simplicity of the presentation, we can create multiple vectors $\tilde{o}_0, \dots, \tilde{o}_n$ (see Line 2, Line 9, Line 10). However, every time at i -th, we only need to use the information for \tilde{o}_i which has at most length n size. Thus, a straightforward and better implementation for only using one length- n to store accumulative score can reduce n^2 usage to n .

F.7. Explaining Submodular Diminishing Return Property in Attention Scheme

In the standard submodular problem (Schrijver, 2003), we are given a ground set $[n]$ and a function $f : 2^{[n]} \rightarrow \mathbb{R}$. The goal is to find a set of elements S such that $f(S)$ is maximized.

We say function f is submodular (Recall the formal definition in Definition F.1), if for every $X, Y \subset [n]$ with $X \subseteq Y$ and every $x \in [n] \setminus Y$ we have

$$f(X \cup \{x\}) - f(X) \geq f(Y \cup \{x\}) - f(Y)$$

Submodular functions can represent the cost of items, due to their diminishing returns property (Krause & Guestrin, 2008; Bilmes, 2015). It suggests that the increase in information obtained from selecting a candidate object, such as a word or sentence, becomes smaller as more objects have already been chosen for the summary.

For instance, we introduce a new token, denoted as “w”, into two sets, S and S_0 , where the concepts covered by S_0 are a subset of those covered by S . By intuition, the information added to S_0 by “w” should be larger compared to adding it to S , as the new concepts carried by “w” might have already been covered by the concepts present in S but not in S_0 . This property is known as the diminishing return property. Hence, we propose that the neural coverage function (Han et al.,

2019b) should exhibit a desirable characteristic called submodularity.

F.8. Submodular: High Level Ideas

We formalize the submodular function maximization problem with cardinality constraint in this section. Informally, a set function is submodular if it has decreasing marginal increment.

Definition F.16 (Submodular function). We denote $f : 2^{[n]} \rightarrow \mathbb{R}$ as a set function. The discrete derivative Δ_f is defined as follows:

$$\Delta_f(i | S) := f(S \cup \{i\}) - f(S).$$

A function f is submodular if, for any $S \subseteq T$ and $i \in [n] \setminus T$, the following inequality holds:

$$\Delta_f(i | T) \leq \Delta_f(i | S).$$

For simplicity, we present the problem of maximizing a submodular function with a cardinality constraint (1). Our goal is to solve the optimization problem efficiently.

$$\begin{aligned} \max_{S \subseteq [n]} \quad & f(S) \\ \text{s.t.} \quad & |S| \leq k \end{aligned} \tag{1}$$

Representation of $f(S)$ One challenge in designing the algorithm is determining the representation of input instances. Since the constraint in optimization problem (1) is straightforward, we need to decide how to represent $f(S)$. Suppose $S = i_1, i_2, \dots, i_m \subseteq [n]$, we can decompose $f(S)$ into a sum of increments as follows:

$$f(S) = f(S_0) + \sum_{j=1}^m (f(S_j) - f(S_{j-1})), \tag{2}$$

where $S_0 = \emptyset$ and $S_j = S_{j-1} \cup i_j$. Without loss of generality, we assume $f(\emptyset) = 0$. By the definition of $\Delta_f(i|S)$, we have $f(S_j) - f(S_{j-1}) = \Delta_f(i_j | S_{j-1})$. Therefore, the decomposition (2) can be simplified as follows:

$$f(S) = \sum_{j=1}^m \Delta_f(i_j | S_{j-1}) \tag{3}$$

To introduce our advanced data structure later, we further represent $\Delta_f(i|S)$ in the form of

$$\Delta_f(i|S) = u_i^\top h(S) u_i \tag{4}$$

where $u_i \in \mathbb{R}^d$ is a d -dimensional vector and $h(S) \in \mathbb{R}^{d \times d}$ is a d -by- d matrix.

In practice, a significant subclass of submodular functions is the monotone submodular functions, i.e. functions f satisfying $f(A) \leq f(B)$ for all $A \subseteq B \subseteq [n]$. When f is monotone, we could restrict all $h(S)$ to be positive semidefinite (PSD) matrixes. When the matrix $h(S)$ is positive semidefinite (PSD), it makes us achieve a faster acceleration.

F.9. Robust Greedy with Error Propagation

The procedure for the greedy selection algorithm initiates with empty set $S_0 = \emptyset$. For each iteration in the main loop, the algorithm chooses the element that maximizes the marginal increment to add to the set. When the size of the set eventually reaches k , the algorithm return that set S . Specifically, for iteration $t \in \{1, 2, \dots, k\}$, we let

$$S_t \leftarrow S_{t-1} \cup \{j_t\}$$

where the element in the singleton is $j_t = \arg \max_{j \in \bar{S}_{t-1}} f(S_{t-1} \cup \{j\})$. The greedy strategy is effective in the sense that the approximation error of it is $1 - 1/e$.

Theorem F.17 ((Nemhauser et al., 1978)). *For a monotone submodular function f , the greedy algorithm (Algorithm 3) guarantees to output a set S satisfying*

$$f(S) \geq (1 - 1/e) \max_{|T|=k} \{f(T)\}.$$

Algorithm 3 Greedy algorithm benchmark

```

1: procedure GREEDYALGORITHM(submodular function  $f$ )
2:    $S_0 \leftarrow \emptyset$  ▷ Initialize an empty set  $S_0$ 
3:   for  $t = 0 \rightarrow k - 1$  do
4:      $j \leftarrow \arg \max_i \{f(S_t \cup \{i\})\}$  ▷ Find the element  $i \in [n]$  that maximize  $f(S_t \cup \{i\})$ 
5:      $S_{t+1} \leftarrow S_t \cup \{j\}$  ▷ Append element  $i$  to set  $S_t$  to get  $S_{t+1}$ 
6:   end for
7:   return  $S_k$ 
8: end procedure
    
```

Corollary F.18 ((Qin et al., 2023)). Given

- accuracy parameter $\epsilon > 0$.
- integer $k \geq 1$
- Let O denote an oracle that takes an arbitrary set $S \subseteq [n]$ and $i \in [n] \setminus S$, returns a value $O(S, i)$ with guarantee that $\Delta(i|S) - \epsilon \leq O(S, i) \leq \Delta(i|S) + \epsilon$.
- Let A denote an algorithm that each time step $t = 1, 2, \dots, k$, it selects $j_t = \arg \max_j \{O(S_{t-1}, j)\}$ and lets $S_t \leftarrow S_{t-1} \cup \{j_t\}$.

Then this algorithm A

- returns a set S_k
- the S_k satisfy that

$$f(S_k) \geq (1 - 1/e) \max_{|T|=k} \{f(T)\} - k(2 - 1/e)\epsilon.$$

F.10. Robust Submodular and Adding Items

We first propose a lemma that shows the robustness of the submodular.

Lemma F.19. Suppose that for each $i \in [n]$, we have

- for all $S_i \subset [n]$ with $|S_i| \leq k$
- for all $X \subset [n]$, $X \subseteq S_i \cup \{i\}$ and $|X \cap S_i| \leq |S_i|$,

$$|(\tilde{f}_{S_i, i}(X)) - \tilde{f}_{S_i, i}(S_i) - (f_{S_i, i}(X) - f_{S_i, i}(S_i))| \leq \epsilon/(2n)$$

Let opt_i denote the optimal cost that can be achieved by using f in i -th iteration. If the greedy algorithm use f to find the solution has performance at least $(1 - 1/e) \cdot \text{opt}_i$, then using \tilde{f} , we can obtain a solution that has performance at least $(1 - 1/e) \cdot \text{opt}_i - \epsilon$

Proof. The proof follows from Lemma F.18. □

Next, we explain how to add items into sets based on exact values.

Definition F.20 (Expanding items based on exact value). If the following conditions hold

- Let $S_i \subseteq [i - 1]$.
- Let $f_{S_i, i} : 2^{[i]} \rightarrow \mathbb{R}$.

Then, we can define S_{i+1} as follows

- If $|S_i| = k$ then $S_{i+1} = S_i \cup \{i\} \setminus u$ where $u = \arg \max_{v \in S_i \cup \{i\}} f_{S_i, i}(S_i \cup \{i\} \setminus v) - f_{S_i, i}(S_i)$
- If $|S_i| < k$, then $S_{i+1} = S_i \cup \{i\}$.

Remark F.21. We remark that $u = \arg \max_{v \in S_i \cup \{i\}} f_{S_i, i}(S_i \cup \{i\} \setminus v) - f_{S_i, i}(S_i)$ is the same as $u = \arg \max_{v \in S_i \cup \{i\}} f_{S_i, i}(S_i \cup \{i\} \setminus v)$. For the convenience of discussion and analysis, we will switch to using both cases in different places.

Here, we explain how to add items into sets via approximate values.

Definition F.22 (Expanding items based on approximate value). If the following conditions hold

- Let $S_i \subseteq [i - 1]$.
- Let $\tilde{f}_{S_i, i} : 2^{[i]} \rightarrow \mathbb{R}$.

Then, we can define S_{i+1} as follows

- If $|S_i| = k$ then $S_{i+1} = S_i \cup \{i\} \setminus u$ where $u = \arg \max_{v \in S_i \cup \{i\}} \tilde{f}_{S_i, i}(S_i \cup \{i\} \setminus v) - \tilde{f}_{S_i, i}(S_i)$
- If $|S_i| < k$, then $S_{i+1} = S_i \cup \{i\}$.

F.11. Universal Conditions

We state several definitions for both the exact function and approximation function.

Definition F.23 (Universal Monotone Condition (for exact function)). We say f has universal monotone condition, if for all $i \in [n]$ for all $S_i \subseteq [i - 1]$, we have

$$f_{S_i, i}(X) \geq f_{S_i, i}(Y), \quad \forall Y \subset X$$

Definition F.24 (Universal Monotone Condition (for approximate function)). We say \tilde{f} has universal monotone condition, if for all $i \in [n]$ for all $S_i \subseteq [i - 1]$, we have

$$\tilde{f}_{S_i, i}(X) \geq \tilde{f}_{S_i, i}(Y), \quad \forall Y \subset X$$

Definition F.25 (Universal Dynamic Condition 1 (for exact function)). We say f has universal dynamic condition 1 (for exact function), if for all $i \in [n]$ for all $S_i \subseteq [i - 1]$, $S_{i-1} \subseteq [i - 2]$, $|S_i \setminus S_{i-1}| \leq 1$, we have

$$f_{S_i, i}(S_i) \geq (1 - \theta) \cdot f_{S_{i-1}, i-1}(S_i)$$

Definition F.26 (Universal Dynamic Condition 1 (for approximate function)). We say \tilde{f} has universal dynamic condition 1 (for approximate function), if for all $i \in [n]$ for all $S_i \subseteq [i - 1]$, $S_{i-1} \subseteq [i - 2]$, $|S_i \setminus S_{i-1}| \leq 1$, we have

$$\tilde{f}_{S_i, i}(S_i) \geq (1 - \theta) \cdot \tilde{f}_{S_{i-1}, i-1}(S_i)$$

We define opt_i as follows:

Definition F.27. Let k denote the budget length. For each $i \in [n]$, we define opt_i as

$$\max\{f_{X, i}(Y) \mid X \subseteq [i - 1], Y \subseteq [i], |X| \leq k, |Y| \leq k, |Y \setminus X| \leq 1\}.$$

Definition F.28 (Universal Dynamic Condition 2). For $i \in [n]$, we define opt_i as Definition F.27. We say it has universal dynamic condition if for each $i \in [n]$, we have

$$\text{opt}_i \geq (1 - \gamma) \cdot \text{opt}_{i-1}.$$

F.12. Induction Lemma for Exact Function

The goal of this section is to prove Lemma F.29

Lemma F.29 (Induction Lemma). For a fixed i , suppose the following conditions hold

- **Set Condition.** $S_i \subseteq [i - 1]$
- **Budget Condition.** $|S_i| \leq k$
- **Value Condition.** $f_{S_{i-1}, i-1}(S_i) \geq (1 - 1/e) \cdot (1 - \theta)^i (1 - \gamma)^i \text{opt}_i$
- **Universal Dynamic Condition 1 (for exact function).** (See Definition F.25) $f_{S_i, i}(S_i) \geq (1 - \theta) \cdot f_{S_{i-1}, i-1}(S_i)$
- **Universal Dynamic Condition 2.** (See Definition F.28) $\text{opt}_i \geq (1 - \gamma) \cdot \text{opt}_{i+1}$
- **Universal Monotone Condition (for exact function).** (See Definition F.23) $f_{S_i, i}(X) \geq f_{S_i, i}(Y)$ for all $Y \subset X$

Then if we construct S_{i+1} as Definition F.20, then we have

- **Set Condition.** $S_{i+1} \subseteq [i]$
- **Budget Condition.** $|S_{i+1}| \leq k$
- **Value Condition.** $f_{S_i, i}(S_{i+1}) \geq (1 - 1/e) \cdot (1 - \theta)^{i+1} (1 - \gamma)^{i+1} \text{opt}_{i+1}$

Proof. **Proof of Set Condition.**

Note that $S_i \subseteq [i - 1]$, by using the way we construct S_{i+1} , then it is obvious that $S_{i+1} \subseteq [i]$.

Proof of Budget Condition.

Note that $|S_i| \leq k$, by using the way we construct S_{i+1} , then it is straightforward that $|S_{i+1}| \leq k$.

Proof of Value Condition.

We can show that

$$\begin{aligned}
 f_{S_i, i}(S_{i+1}) &\geq f_{S_i, i}(S_i) \\
 &\geq (1 - \theta) \cdot f_{S_{i-1}, i-1}(S_i) \\
 &\geq (1 - \theta) \cdot ((1 - 1/e)(1 - \theta)^i (1 - \gamma)^i \text{opt}_i - i \cdot \epsilon_0) \\
 &\geq (1 - \theta) \cdot ((1 - 1/e)(1 - \theta)^i (1 - \gamma)^{i+1} \text{opt}_{i+1}) \\
 &\geq (1 - 1/e) \cdot (1 - \theta)^{i+1} (1 - \gamma)^{i+1} \text{opt}_{i+1}.
 \end{aligned}$$

where the first step follows from **Universal Monotone Condition**, the second step follows from **Universal Dynamic Condition 1**, the third step follows from **Value Condition**, the forth step follows from **Universal Dynamic Condition 2**, and the last step follows from simple algebra.

Thus, we complete the proof. \square

F.13. Induction Lemma for Approximate Function

The goal of this section is to prove Lemma F.30

Lemma F.30 (Induction Lemma). For a fixed i , suppose the following conditions hold

- **Set Condition.** $S_i \subseteq [i - 1]$
- **Budget Condition.** $|S_i| \leq k$
- **Value Condition.** $f_{S_{i-1}, i-1}(S_i) \geq (1 - 1/e) \cdot (1 - \theta)^i (1 - \gamma)^i \text{opt}_i - i \cdot \epsilon_0$

- **Universal Dynamic Condition 1 (for approximate function).** (see Definition F.26) $\tilde{f}_{S_i,i}(S_i) \geq (1 - \theta) \cdot \tilde{f}_{S_{i-1},i-1}(S_i)$
- **Universal Dynamic Condition 2.** $\text{opt}_i \geq (1 - \gamma) \cdot \text{opt}_{i+1}$
- **Universal Approximate Condition.** (See Definition F.28) $f_{S_i,i}(X) \geq \tilde{f}_{S_i,i}(X) - \epsilon_0$ for all X
- **Universal Monotone Condition (for approximate function).** (see Definition F.24) $\tilde{f}_{S_i,i}(X) \geq \tilde{f}_{S_i,i}(Y)$ for all $Y \subset X$

Then if we construct S_{i+1} as Definition F.22, then we have

- **Set Condition.** $S_{i+1} \subseteq [i]$
- **Budget Condition.** $|S_{i+1}| \leq k$
- **Value Condition.** $f_{S_i,i}(S_{i+1}) \geq (1 - 1/e) \cdot (1 - \theta)^{i+1}(1 - \gamma)^{i+1}\text{opt}_{i+1} - (i + 1) \cdot \epsilon_0$

Proof. **Proof of Set Condition.**

Note that $S_i \subseteq [i - 1]$, by using the way we construct S_{i+1} , then it is obvious that $S_{i+1} \subseteq [i]$.

Proof of Budget Condition.

Note that $|S_i| \leq k$, by using the way we construct S_{i+1} , then it is straightforward that $|S_{i+1}| \leq k$.

Proof of Value Condition.

We can show that

$$\begin{aligned}
 f_{S_i,i}(S_{i+1}) &\geq \tilde{f}_{S_i,i}(S_{i+1}) - \epsilon_0 \\
 &\geq \tilde{f}_{S_i,i}(S_i) - \epsilon_0 \\
 &\geq (1 - \theta) \cdot \tilde{f}_{S_{i-1},i-1}(S_i) - \epsilon_0 \\
 &\geq (1 - \theta) \cdot ((1 - 1/e)(1 - \theta)^i(1 - \gamma)^i\text{opt}_i - i \cdot \epsilon_0) - \epsilon_0 \\
 &\geq (1 - \theta) \cdot ((1 - 1/e)(1 - \theta)^i(1 - \gamma)^{i+1}\text{opt}_{i+1} - i \cdot \epsilon_0) - \epsilon_0 \\
 &\geq (1 - 1/e) \cdot (1 - \theta)^{i+1}(1 - \gamma)^{i+1}\text{opt}_{i+1} - (i + 1) \cdot \epsilon_0.
 \end{aligned}$$

where the first step follows from **Universal Approximate Condition**, the second step follows from **Universal Monotone Condition**, the third step follows from **Universal Dynamic Condition 1**, the forth step follows from **Value Condition**, the fifth step follows from **Universal Dynamic Condition 2**, and the last step follows from simple algebra.

Thus, we complete the proof. \square

F.14. Theoretical Result

We first give the guarantee of our full-knowledge version (without cache size limitation).

Lemma F.31 (Formal version of Lemma 3.1). Under the mild assumption, let k denote any target size. If we greedily compute the attention score based on full information, then we can find the set S_i such that

$$f(S_i) \geq (1 - 1/e) \cdot (1 - \alpha)\text{opt}_i,$$

where $\alpha \in (0, 1)$ are parameters.

Proof. The proof follows from using Theorem F.17, Corollary F.18, Lemma F.29 with choosing $\theta = \gamma = \alpha/(10n)$. \square

Next, we show the guarantee for our robust and approximate greedy eviction policy algorithm (Algorithm 2).

Theorem F.32 (Formal version of Theorem 4.4). *Under the mild assumption, let k denote the budget of space limitation. If for each token, we greedily compute the attention score based on top- k choice, then we can show the set \tilde{S}_i we generate each for token $i \in [n]$ satisfy that*

$$f(\tilde{S}_i) \geq (1 - 1/e) \cdot (1 - \alpha) \text{opt}_i - \beta,$$

where $\alpha \in (0, 1), \beta > 0$ are parameters.

Proof. The proof follows from using Theorem F.17, Corollary F.18, Lemma F.30 with choosing $\epsilon_0 = \beta/(10n)$ and $\theta = \gamma = \alpha/(10n)$. \square

F.15. Extended Related Work for Theoretical Attention Problems

The static attention computation is asking the following question that given $Q, K, V \in \mathbb{R}^{n \times d}$, the goal is to $D^{-1} \exp(QK^\top)V$ where $D = \text{diag}(\exp(QK^\top)\mathbf{1}_n)$. (Alman & Song, 2023) studied the static attention computation from both algorithm and hardness. On the positive, they provide an almost linear time algorithm to approximately compute the attention matrix. On the negative side, assuming a strong exponential time hypothesis (SETH), they prove a hardness result. Their hardness result is, unless SETH fails, there is no algorithm that runs in truly subquadratic time to approximately compute the attention matrix. Further, (Brand et al., 2023) considers the dynamic of attention computation problem. They also provide both algorithmic results and hardness results. In the work of (Deng et al., 2023b), they consider the sparsification of attention matrix construction. In particular, they assume that situation that $d \gg n$, and show how to sparsify the columns of matrix Q . (Deng et al., 2023b) provides two algorithms, one is a randomized algorithm, and the other is a deterministic algorithm. Differential privacy is a famous and textbook topic in graduate school, recently the work of (Gao et al., 2023a) shows how to give a differentially private algorithm for computing the attention matrix. For a given $A \in \mathbb{R}^{n \times d}$ and vector $b \in \mathbb{R}^n$, (Li et al., 2023b) formulates and studies exponential regression $\min_x \|\exp(Ax) - b\|_2$. Then (Deng et al., 2023a) considers the normalization factor in exponential regression and defines the softmax regression problem $\min_x \|\langle \exp(Ax), \mathbf{1}_n \rangle^{-1} \exp(Ax) - b\|_2$. (Gao et al., 2023b) moves the scaling factor from $\exp(Ax)$ to b and defines a rescaled softmax regression problem $\min_x \|\exp(Ax) - \langle \exp(Ax), \mathbf{1}_n \rangle \cdot b\|_2$.

F.16. Sparsity Preserving

Recall that in Figure 2, we observe that even when trained densely, the attention matrices of LLMs are over 95% sparse at inference time. Only 5% of the KV cache is sufficient for decoding the same output token at each generation step. Here, we provide some formal formulations for sparsity.

Definition F.33. Suppose the following conditions

- Let $S_0 \subset [m]$.
- Let $k = |S_0|$.
- Let $\tau \in (0, 1)$ denote a threshold for truncating the value.
- Let $\alpha \in (0, 1)$ denote a fraction of mass (larger than τ) outside S_0 .
- Let mapping $\mathcal{D} : \mathbb{R}^d \rightarrow \mathbb{R}_{\geq 0}^m$.
- For each $x \in \mathbb{R}^d$, $\mathcal{D}(x) \in \mathbb{R}^m$ is a vector that has length m .

We say the distribution \mathcal{D} is (α, τ, k) -good if the following conditions hold

- For all $x \in \mathbb{R}^d$, $S_0 \subset \text{supp}_\tau(\mathcal{D}(x))$
- For all $x \in \mathbb{R}^d$, $|\text{supp}_\tau(\mathcal{D}(x)) \setminus S_0| \leq \alpha \cdot k$

Claim F.34. Suppose we sample n points $\{x_1, x_2, \dots, x_n\} \subset \mathbb{R}^d$ from (α, τ, k) -good distribution uniformly at random, then we have

- $S_0 \subseteq \cap_{i \in [n]} \text{supp}_\tau(x_i)$
- $|(\cup_{i \in [n]} \text{supp}_\tau(\mathcal{D}(x))) \setminus S_0| \leq \alpha kn$

Proof. Since for all $i \in [n]$, we have $S_0 \subseteq \text{supp}_\tau(\mathcal{D}(x_i))$, thus

$$S_0 \subseteq \cap_{i \in [n]} \text{supp}_\tau(x_i).$$

Therefore we proved the first property.

We know that for all $i \in [n]$, we have $|\text{supp}_\tau(\mathcal{D}(x)) \setminus S_0| \leq \alpha kn$. Thus

$$|(\cup_{i \in [n]} \text{supp}_\tau(\mathcal{D}(x_i))) \setminus S_0| \leq \sum_{i=1}^n |\text{supp}_\tau(\mathcal{D}(x_i)) \setminus S_0| \leq n \cdot \alpha k$$

Therefore, we finish the proof for the second property. \square

F.17. Definition of Loss Function

In this section, we follow the theoretical softmax regression literature (Deng et al., 2023a) and define a number of functions to make the calculations of gradient and Hessian convenient. We also proposed a new penalty term (ℓ_1 type sparsity penalty, see Definition F.41) into the final loss function, which is not studied in previous work (Li et al., 2023b; Deng et al., 2023a; Gao et al., 2023b; Sinha et al., 2023; Wu et al., 2023; Li et al., 2023a). We first provide some function definitions.

Definition F.35 (Function u , (Deng et al., 2023a)). Given matrix $A \in \mathbb{R}^{n \times d}$, let function $u : \mathbb{R}^d \rightarrow \mathbb{R}^n$ be defined as follows

$$u(x) := \exp(Ax)$$

Definition F.36 (Function α , see Definition 5.4 in (Deng et al., 2023a) as an example). We define $u(x)$ as Definition F.35. Then we define $\alpha : \mathbb{R}^d \rightarrow \mathbb{R}$ as follows

$$\alpha(x) := \langle u(x), \mathbf{1}_n \rangle$$

Definition F.37 (Function f , see Definition 5.1 in (Deng et al., 2023a) as an example). Provided that the following conditions are true

- We define $u(x)$ as Definition F.35.
- We define $\alpha(x)$ as Definition F.36

Let function $f : \mathbb{R}^d \rightarrow \mathbb{R}^n$ be defined as follows

$$f(x) := \alpha(x)^{-1} u(x).$$

Definition F.38 (Function c , see Definition 5.5 in (Deng et al., 2023a) as an example). Provided that the following conditions are true

- Given a vector $b \in \mathbb{R}^n$.
- Let $f(x)$ be defined as Definition F.38.

Then, let function $c : \mathbb{R}^d \rightarrow \mathbb{R}^n$ defined as follows

- $c(x) := f(x) - b$.

Definition F.39 (Loss function L_{exp} , see Definition 5.3 in (Deng et al., 2023a) as an example). We define $L_{\text{exp}} : \mathbb{R}^d \rightarrow \mathbb{R}$

$$L_{\text{exp}}(x) := 0.5 \cdot \|c(x)\|_2^2.$$

Definition F.40 (Loss function L_{reg}). Given $A \in \mathbb{R}^{n \times d}$.

Let function $L_{\text{reg}} : \mathbb{R}^d \rightarrow \mathbb{R}$ be defined as follows

$$L_{\text{reg}}(x) := 0.5 \cdot \|\text{diag}(w)Ax\|_2^2$$

We define a novel penalty function

Definition F.41 (Implicitly controlling the sparsity). Given $A \in \mathbb{R}^{n \times d}$.

We define

$$L_{\text{sparse}}(x) := \|\exp(Ax)\|_1.$$

Then it is obvious that we have

Claim F.42. Given $A \in \mathbb{R}^{n \times d}$. Let u be defined as Definition F.35. Let α be defined as Definition F.36.

We have

- $L_{\text{sparse}}(x) = \langle \exp(Ax), \mathbf{1}_n \rangle$
- $L_{\text{sparse}}(x) = \langle u(x), \mathbf{1}_n \rangle$
- $L_{\text{sparse}}(x) = \alpha(x)$

Proof. The proof is trivially following from the definition of $u(x)$ (see Definition F.35) and $\alpha(x)$ (see Definition F.36). \square

The final loss function can be defined as follows. Intuitively, we can write attention $D^{-1} \exp(QK^\top)$ into n subproblems where each subproblem can be viewed as one softmax problem.

Definition F.43. If the following conditions hold

- We define L_{exp} as Definition F.39.
- We define L_{reg} as Definition F.40.
- We define L_{sparse} as Definition F.41.

Then we define L function

$$L(x) := L_{\text{exp}}(x) + L_{\text{sparse}}(x) + L_{\text{reg}}(x).$$

F.18. Gradient

Next, we show the gradient of L_{exp} .

Lemma F.44 (Gradient, Lemma 5.6 in (Deng et al., 2023a)). Provided that the following conditions are true

- Given matrix $A \in \mathbb{R}^{n \times d}$ and a vector $b \in \mathbb{R}^n$.
- Let $A_{*,i} \in \mathbb{R}^n$ denote the i -th column of matrix A , for every $i \in [d]$.
- We define $\alpha(x)$ as Definition F.36.
- We define $f(x)$ as Definition F.37.
- We define $c(x)$ as Definition F.38.
- We define $L_{\text{exp}}(x)$ as Definition F.39.
- Let \circ denote hadamard product.

For every $i \in [d]$, we have

- Part 1.

$$\frac{d \exp(Ax)}{dx_i} = \exp(Ax) \circ A_{*,i}$$

- Part 2.

$$\frac{d \langle \exp(Ax), \mathbf{1}_n \rangle}{dx_i} = \langle \exp(Ax), A_{*,i} \rangle$$

- Part 3.

$$\frac{d\alpha(x)^{-1}}{dx_i} = -\alpha(x)^{-1} \cdot \langle f(x), A_{*,i} \rangle$$

- Part 4.

$$\frac{df(x)}{dx_i} = \frac{dc(x)}{dx_i} = -\langle f(x), A_{*,i} \rangle \cdot f(x) + f(x) \circ A_{*,i}$$

- Part 5.

$$\frac{dL_{\exp}(x)}{dx_i} = A_{*,i}^\top \cdot (f(x)(f(x) - b)^\top f(x) + \text{diag}(f(x))(f(x) - b))$$

F.19. Hessian

Here, we compute the Hessian for several functions.

Lemma F.45 (Hessian of $u(x)$, Lemma 5.9 in (Deng et al., 2023a)). Provided that the following conditions are true

- Given a matrix $A \in \mathbb{R}^{n \times d}$.
- For every $i \in [d]$, let $A_{*,i} \in \mathbb{R}^n$ denote the i -th column of matrix A .
- Let \circ denote hadamard product.

Then, we have, for each $i \in [d]$

- Part 1.

$$\frac{d^2 \exp(Ax)}{dx_i^2} = A_{*,i} \circ u(x) \circ A_{*,i}$$

- Part 2.

$$\frac{d^2 \exp(Ax)}{dx_i dx_j} = A_{*,j} \circ u(x) \circ A_{*,i}$$

Lemma F.46 (Lemma 5.10 in (Deng et al., 2023a)). Provided that the following conditions are true

- We define $\alpha(x)$ as Definition F.36.
- For every $i \in [d]$, let $A_{*,i} \in \mathbb{R}^n$ denote the i -th column of matrix A .
- Let \circ denote hadamard product.

Then, we have

- Part 1.

$$\frac{d^2\alpha(x)}{dx_i^2} = \langle u(x), A_{*,i} \circ A_{*,i} \rangle$$

- Part 2.

$$\frac{d^2\alpha(x)}{dx_i dx_j} = \langle u(x), A_{*,i} \circ A_{*,j} \rangle$$

- Part 3.

$$\frac{d^2\alpha(x)}{dx^2} = A^\top \text{diag}(u(x))A$$

F.20. Hessian is Positive Definite

It is well known that in literature (Li et al., 2023b; Deng et al., 2023a; Gao et al., 2023b), the Hessian H of loss function can be written as $A^\top (B(x) + W^2)A$ for some matrix function $B(x) \in \mathbb{R}^{n \times n}$ (for example see explanation in Section 5.10 in (Deng et al., 2023a)). In this section, we show that Hessian is positive definite.

Lemma F.47. If the following conditions hold

- Given matrix $A \in \mathbb{R}^{n \times d}$.
- We define $L_{\text{sparse}}(x)$ as Definition F.41.
- We define $L_{\text{sparse}}(x)$ Definition F.40.
- We define $L_{\text{sparse}}(x)$ Definition F.39.
- Let $L(x) = L_{\text{exp}}(x) + L_{\text{sparse}}(x) + L_{\text{reg}}(x)$.
- Let $A^\top (B(x) + W^2)A$ be the Hessian of $L(x)$
- Let $W = \text{diag}(w) \in \mathbb{R}^{n \times n}$. Let $W^2 \in \mathbb{R}^{n \times n}$ denote the matrix that i -th diagonal entry is $w_{i,i}^2$.
- Let $\sigma_{\min}(A)$ denote the minimum singular value of A .
- Let $l > 0$ denote a scalar.

Then, we have

- Part 1. If all $i \in [n]$, $w_i^2 \geq 20 + l/\sigma_{\min}(A)^2$, then

$$\frac{d^2 L}{dx^2} \succeq l \cdot I_d$$

- Part 2 If all $i \in [n]$, $w_i^2 \geq 200 \cdot \exp(R^2) + l/\sigma_{\min}(A)^2$, then

$$(1 - 1/10) \cdot (B(x) + W^2) \preceq W^2 \preceq (1 + 1/10) \cdot (B(x) + W^2)$$

Proof. The entire proof framework follows from (Li et al., 2023b; Deng et al., 2023a; Gao et al., 2023b), in the next few paragraphs, we mainly explain the difference.

The $B(x)$ based on L_{sparse} is $\text{diag}(u(x))$. Note that it is obvious that

$$\text{diag}(u(x)) \succeq 0.$$

From the upper bound size, we know that

$$\begin{aligned}\text{diag}(u(x)) &\preceq \|u(x)\|_\infty \cdot I_n \\ &\preceq \exp(R^2)\end{aligned}$$

where the last step follows from Proof of Part 0 in Lemma 7.2 in (Deng et al., 2023a).

To prove Part 1, following from (Li et al., 2023b; Deng et al., 2023a), we only use the lower bound of $\text{diag}(u(x))$. By putting things together, we get our results.

To prove Part 2, we follow from (Gao et al., 2023b) and use both the upper bound and lower bound of $\text{diag}(u(x))$. □

F.21. Hessian is Lipschitz

In this section, we show Hessian is Lipschitz.

Lemma F.48. If the following conditions hold

- Let $H(x) = A^\top(B(x) + W^2)A$ denote the Hessian of L .

Then, we have

$$\|H(x) - H(y)\| \leq n^2 \exp(40R^2) \|x - y\|_2$$

Proof. The entire proof framework follows from (Li et al., 2023b; Deng et al., 2023a; Gao et al., 2023b), in the next few paragraphs, we mainly explain the difference.

Note that the $B(x)$ based on $L_{\text{exp}} + L_{\text{reg}}$ have been proved by (Deng et al., 2023a)

We only need to prove $B(x)$ based on L_{sparse} and add them together.

Note that $B(x)$ based on L_{sparse} is in fact $\text{diag}(u(x))$.

Using Lemma 7.2 in (Deng et al., 2023a), we know that

$$\begin{aligned}\|\text{diag}(u(x)) - \text{diag}(u(y))\| &\leq \|u(x) - u(y)\|_2 \\ &\leq 2\sqrt{n}R \exp(R^2) \|x - y\|_2\end{aligned}$$

where the last step follows from Part 1 in Lemma 7.2 in (Deng et al., 2023a).

Thus, putting things together, we complete the proof. □

F.22. Greedy Type Algorithm

In this section, we propose a greedy-type algorithm (based on the approximate Newton method) to solve the optimization problem.

Theorem F.49. Given matrix $A \in \mathbb{R}^{n \times d}$, $b \in \mathbb{R}^n$, and $w \in \mathbb{R}^n$.

- We use x^* to denote the optimal solution of

$$\min_{x \in \mathbb{R}^d} L_{\text{exp}} + L_{\text{sparse}} + L_{\text{reg}}$$

that

- $g(x^*) = \mathbf{0}_d$, where g denotes the gradient function.
- $\|x^*\|_2 \leq R$.

- Suppose that $R \geq 10$, $M = \exp(\Theta(R^2 + \log n))$, and $l > 0$.

Algorithm 4 A greedy type algorithm.

```

1: procedure OURITERATIVEMETHOD( $A \in \mathbb{R}^{n \times d}, b \in \mathbb{R}^n, w \in \mathbb{R}^n, \epsilon, \delta$ )
2:   Initialize  $x_0$ 
3:    $T \leftarrow \log(\|x_0 - x^*\|_2 / \epsilon)$  ▷ Let  $T$  denote the number of iterations.
4:   for  $t = 0 \rightarrow T$  do
5:      $D \leftarrow B_{\text{diag}}(x_t) + \text{diag}(w \circ w)$ 
6:      $\tilde{D} \leftarrow \text{SUBSAMPLE}(D, A, \epsilon_1 = \Theta(1), \delta_1 = \delta/T)$ 
7:     Compute gradient  $g$  exactly
8:     Get the approximate Hessian  $\tilde{H}$  by computing  $A^\top \tilde{D} A$ 
9:     Update  $x_{t+1}$  by using the Newton step  $x_t + \tilde{H}^{-1}g$ 
10:  end for
11:   $\tilde{x} \leftarrow x_{T+1}$

- Assume that $\|A\| \leq R$. Here $\|A\|$ denotes the spectral norm of matrix A .
- Suppose that $b \geq \mathbf{0}_n$ and $\|b\|_1 \leq 1$. Here $\mathbf{0}_n$ denotes a length- n vector where all the entries are zeros. (Here $b \geq \mathbf{0}_n$ denotes $b_i \geq 0$ for all $i \in [n]$)
- Assume that $w_i^2 \geq 200 \cdot \exp(R^2) + l/\sigma_{\min}(A)^2$ for all $i \in [n]$. Here $\sigma_{\min}(A)$ denotes the smallest singular value of matrix A .
- Let x_0 denote an starting/initial point such that $M\|x_0 - x^*\|_2 \leq 0.1l$.
- We use to $\epsilon \in (0, 0.1)$ represent our accuracy parameter.
- We use $\delta \in (0, 0.1)$ to represent failure probability.

There is a randomized algorithm that

- runs $\log(\|x_0 - x^*\|_2 / \epsilon)$ iterations
- spend

$$O((\text{nnz}(A) + d^\omega) \cdot \text{poly}(\log(n/\delta)))$$

time per iteration,

- and finally outputs a vector $\tilde{x} \in \mathbb{R}^d$ such that

$$\Pr[\|\tilde{x} - x^*\|_2 \leq \epsilon] \geq 1 - \delta.$$

Proof. The proof framework follows from (Li et al., 2023b; Deng et al., 2023a; Gao et al., 2023b; Sinha et al., 2023).

Following from Lemma F.47, we know the Hessian of the loss function is positive definite.

Following from Lemma F.48, we know the Hessian of L is Lipschitz.

Following Section 9 in (Deng et al., 2023a), by running Algorithm 4, we complete the proof.

□

We remark that ω denotes the exponent of matrix multiplication (i.e., n^ω is the time of multiplying an $n \times n$ matrix with another $n \times n$ matrix). The most naive algorithm gives $\omega = 3$. Currently, the state-of-the-art algorithm gives $\omega = 2.373$.
